Ataxic dysarthria is associated with lesion's disturbances of the cerebellum or its controls. As it is known for its incoordination as a characteristic, individuals are perceived with articulation and prosodic feature disturbances. Irregular articulatory breakdowns, distorted vowels, and inappropriate variations in pitch, loudness, and stress often are the classic features (14).

This type of dysarthria has been coined with the term "drunken speech." Ataxic dysarthria is often a result of cerebellar stroke or spinocerebellar ataxia.

### **Hypokinetic Dysarthria**

Hypokinetic dysarthria is associated with basal ganglia control of the central nervous system. Its features are mostly related

to reduce range of motion and rigidity. Additionally, reduced loudness, short rushes of speech, breathy-tight dysphonia, and monoloudness and monopitch are notable characteristics. Often dysfluency and word repetition are reported. Parkinson's disease and its syndromes are the most noted disorder for hypokinetic dysarthria (15).

### **Hyperkinetic Dysarthria**

Hyperkinetic dysarthria is also associated with basal ganglia control; however, unlike hypokinetic dysarthrias, it is distinguished by abnormal involuntary movements that affect the intended speech movements. It is classified in many of the movement disorders and subcategorized into slow and fast hyperkinetic dysarthrias. Slow includes dystonia and athetosis, while fast includes tic and chorea. They may affect any of the speech systems and area usually distinguished by unpredictable variability in voice and articulation. Distorted vowels, excess loudness variations, sudden forced inspiration/expiration, voice stoppages/arrests, transient breathiness, intermittent hypernasality, and inappropriate vocal noises are just some of the common characteristics. Etiologies include Huntington's chorea, Tourette's syndrome, cerebral palsy, and side effects of neuroleptic drugs (16).

### **Unilateral Upper Motor Neuron Dysarthria**

This dysarthria has an anatomical rather than a pathophysiological label. It typically results from stroke affecting upper neuron pathways. Damage is unilateral; severity usually is rarely worse than mild to moderate. Often its characteristics overlap with flaccid, spastic, or ataxic dysarthrias (16).

### **Mixed Dysarthria**

Mixed dysarthria reflects combinations of two or more of the single dysarthria type. It occurs more frequently than any single dysarthria type. A common diagnosis involving mixed dysarthria is amyotrophic lateral sclerosis, which, in advanced stages, has features of both flaccid and spastic dysarthrias (15).

### **Assessment**

Traditionally, the assessment of dysarthric speech has mainly involved the use of perceptual evaluation measures. The inadequacies of this method of assessment have resulted in the development of a range of instrumental assessment techniques to provide more objective analyses of the underlying physiological impairments of the speech mechanism. Generally, the assessment of dysarthria relies on a combination of perceptual and instrumental analysis, including acoustic analyses. Most of the perceptual scales are based on the studies by Darley et al., using a number of speech dimensions to be rated on a severity rating scale (14). Intelligibility scores has been one of the main measurement parameters to indicate communicative functional status. The interactive product of respiration, phonation, articulation, resonance, and prosody helps to define the speech impairment and requires full attention during assessments. Often, little attention is placed on connected speech intelligibility in the dysarthria population; however, it may

be a more valid indicator of functional communication than assessment at the word or simple phrase level (17).

Studies have demonstrated acoustic variations in dysarthria; however, many of the studies have focused on one element in acoustic analysis rather than a broadly directed analysis of the speech output by systems, for example the articulatory, resonatory, phonatory, and respiratory components (18–22).

A dysarthric speech assessment must involve perceptual acoustic description of all the systems. Clinicians must understand the interrelationship of the weakness, slowness, discoordination, or abnormal tone of the speech musculature and its effect on the systems of the speech mechanism, including respiratory, phonatory, velopharyngeal, or oral articulatory subsystems (23). Both perceptual and instrumental tools are available for measuring speech performance (24,25). The perceptual tools are those that rely on the trained eyes and ears of the clinician, whereas instrumental approaches to assessment include devices that provide information about the acoustic, aerodynamic movement, or phonatory aspects of speech.

Assessment of the respiratory subsystem begins with perceptual measures, including ratings of the number of words produced per breath, the loudness of samples of connected speech, or visual observations of the presence of clavicular breathing. Instrumental approaches to the measurement of respiratory function may include acoustic measures of vocal intensity and utterance durations. Respiratory performance may also be assessed by estimating the subglottic air pressure generated by the speaker (26,27). Respiratory inductive plethysmography, commercially available as the RespiTrace, is an instrument capable of obtaining information about the movements of the rib cage and abdomen during breathing and speech.

Phonatory (laryngeal subsystem) assessment typically begins with perceptual ratings of pitch characteristics (e.g., pitch level, pitch breaks, monopitch, and voice tremor), loudness (e.g., monoloudness, excess loudness, variation of volume), and voice quality (e.g., harsh voice, hoarseness, wet voice, breathiness, strained-strangled voice). Acoustic analysis can be performed by deriving vocal fundamental frequency and intensity (28,29). Measures of laryngeal resistance to air-flow can also be obtained (30) along with laryngeal visualization with endoscopy or stroboscopy (30).

Assessment of the velopharyngeal mechanism can be made with perceptual judgments of hypernasality or the occurrence of nasal air emission. Nasalization also can be measured acoustically. Precise inferences can be made about the timing of velopharyngeal closure by obtaining simultaneous pneumatic measures of air pressure and air flow during selected speech samples (31,32). Movement of the velopharyngeal mechanism can be observed through cineradiographic techniques and/or endoscopic visualizations.

Assessment of oral articulation can be made by the rating of consonant and vowel precisions and coordination of articulatory movement. Although movements can be recorded using cineradiographic technique and myoelectric activity with

electromyographic recordings, these techniques are not used in routine clinical practice.

### Treatment Considerations

Clinical decisions regarding treatment of dysarthria should include behavioral objectives for reaching short- and long-term goals. An overall goal to improve functional communication for the patient is necessary and should be identified and described with the patient and his or her significant family members. Generally, treatment goals can vary with the severity of the speech impairment and the overall medical disorder.

For severely involved speakers, whose intelligibility is so poor that they are unable to communicate verbally in some or all situations, the general goal of treatment involves establishing an immediate functional means of communication. This may include use of augmentative approaches. The term *communication augmentation* refers to any device designed to augment, supplement, or replace verbal communication for someone who is not an independent verbal communicator. These augmentative or alternative communication (AAC) systems can be as low tech as writing or communication boards, or higher tech such as talk-back switches or computer-based speech synthesis. The selection of an appropriate augmentation system requires a thorough evaluation of the individual's communication needs. To determine an individual's needs, the clinician needs to consider the patient's physical and cognitive capabilities, including cognition, language, memory, physical control, vision, hearing, and overall medical condition. This assessment may require additional co-evaluators, such as an occupational therapist or a rehabilitation engineer. Once the individual's capabilities have been ascertained, augmentative system components can be selected, and appropriate system modifications can be made.

For those moderately involved speakers who are able to use speech as their primary means of communication but whose intelligibility is compromised, the general goal of treatment involves improving intelligibility. Use of compensatory strategies with speech production or augmentative systems is common. Achieving compensated intelligibility may take a variety of forms, depending on the speaker and the nature of the underlying impairment. For some with greater involvement, use of an alphabet supplementation system, in which they point to the first letter of each word as they say the word, assists in the transition to intelligible speech (9). For others, the treatment involves an attempt to decrease the impairment by exercises that will improve performance on selected aspects of speech production. For example, exercises may involve developing more adequate respiratory support for speech (33) or training to establish an appropriate speech rate (34). For the mildly involved dysarthric speaker whose speech is characterized as intelligible but less efficient and less natural than normal, treatment planning should consider the patient's needs in communication within his or her home or job setting. For some speakers, these mild reductions in speech efficiency pose no problems. For other mildly involved speakers, however, treatment is warranted. The general goals of treatment

for dysarthric people with mild disabilities include maximizing communication efficiency while maintaining intelligibility and maximizing speech naturalness. Maximizing naturalness is accomplished by teaching appropriate phrasing, stressing patterning, and intonation (35).

Often partnerships with other medical professionals are appropriate. For example, a maxillofacial prosthodontist may assist with managing resonant disorders such as velopharyngeal incompetence. Fabrication of a prosthetic device such as a palatal lift can assist with management of impaired velopharyngeal closure. Assessment of candidacy for the device is a coordinated effort between the speech-language pathologist and the prosthodontist. An appropriately fitted palatal lift will allow certain dysarthric speakers to better produce speech sounds that require the buildup air pressure and can maximize intelligibility by improving prosody and contextual breath support.

Treatment approaches for patients with progressive disorders such as parkinsonism, multiple sclerosis, and amyotrophic lateral sclerosis are different from those used with the dysarthric speaker who is recovering from a single medical event (36). Initially, the patients are encouraged to maximize the functional communication level by paying specific attention to the clarity and precision of their speech. At some point, the patients will need to modify their speaking patterns by controlling rate and consonant emphasis and by reducing the number of words per breath. Some patients with progressive dysarthria make the adjustments in their speech pattern without specific treatment; others may need to practice these modifications with a speech pathologist or trained family member until the changes become habitual. In severe cases, a communication augmentation system may be considered. These augmentation systems usually are chosen or designed to accommodate the lifestyle of the patient while serving his or her anticipated communication needs over the longest period of time.

### Apraxia

Apraxia of speech (AOS) occurs in the absence of significant weakness and incoordination of muscles, with automatic and reflexive movements undisturbed. Lesions in the premotor cortex are a frequent finding (37). AOS is characterized by labored and dysprosodic productions, resulting in errors of omission, substitution, and repetition. There is debate as to whether AOS is a pure motor or linguistic (i.e., phonemic) disturbance (38–40). Patients have difficulty programming the positioning of the speech musculature and sequencing the movements necessary for speech. It is seen by some as a distinct condition that often coexists and complicates aphasia, whereas others regard the characteristics as part of the nonfluent Broca's aphasia. AOS carries a negative prognosis for recovery when there is a moderate to severe aphasia in tandem. When it occurs without the concomitant language disturbance, therapy can focus on retraining the patient's ability to program sound patterns, to shift from one sound to another, and to use preserved melodic and rhythmic patterns to facilitate speech.

### Head and Neck Cancer

The diagnosis of head and neck cancer often presents with speech and/or swallowing impairments. The location of the malignancy often dictates the speech impairment being phonatory, resonance, articulatory, or a combination of the three. Treatment of the disease can be a sole modality such as surgery or radiation therapy or multiple modalities, including surgery, irradiation, and chemotherapy. Over the last 20 years, treatment has focused on organ preservation with the goal of maintaining function. This type of treatment is often recommended for tumors of the tongue, oral cavity, tonsil, base of tongue, and pharynx and larynx. Depending on tumor size, spread of disease, and nodal involvement, the treatment often involves radiation with or without chemotherapy. Speech impairments thus would typically be seen in the acute phase of treatment and in the immediate posttreatment acute phase (6 months posttreatment). Chronic effects are often seen with scarring and fibrosis greater than 6 months posttreatment.

Often surgical intervention is needed with advanced disease or recurring disease. This may involve removal of the larynx alone or with other organs. Removal of the larynx or total laryngectomy is a common procedure. With loss of the voicing component for speech production, there is an obvious need for speech rehabilitation, beginning with presurgical teaching and continuing with communication alternatives and rehabilitation postsurgery.

Several options for speaking are available to postlaryngectomy patients including artificial larynx, esophageal speech, or tracheal esophageal puncture, a voice restoration procedure. Artificial larynx use or electrolarynx offers individuals the opportunity to speak within days of surgery. Commercially available electrolarynges are designed to introduce air vibrations either directly into the oral cavity through a catheter or indirectly through the neck tissues. In each case, the tones resonate within the oral and pharyngeal cavities and are modified by articulation into audible, intelligible words. Often an intraoral electrolarynx can be used 2 or 3 days after surgery, providing the patient with an immediate means of communication. Intraoral devices can also be used a long term for patients with necks that are unsuitable for indirect transmission of vibration, usually because of pain, edema, or scar tissue. Experience suggests that good speech is slower to develop using an intraoral device than with a neck device. Therefore, care must be taken to help the patient avoid early frustration associated with not being understood immediately.

A second form of speech alternative is esophageal speech. Esophageal speech is accomplished by training the patient to move air from the oral and pharyngeal cavities into the esophagus by injection or inhalation methods. The air is then trapped within the cricopharyngeal segment and released. The vibration of the release from the segment is the phonatory sound that is then modulated with resonatory and articulatory modifications to produce speech. Accomplished esophageal speakers can speak clearly and effortlessly; however, many laryngectomy patients are unable to learn this technique. Failure to learn esophageal speech may represent insufficient or excessive

pharyngoesophageal segment tone, scarring, nerve damage, or reduced patient commitment for learning.

A third option for speech involves surgical intervention and placement of a one-way-valved prosthesis between the trachea and the esophagus. This is termed tracheoesophageal puncture (TEP). The procedure often is performed by head and neck surgeons as a secondary procedure; however, it can be performed with the total laryngectomy. This method of voice production uses the same anatomic vibratory site as the esophageal speech technique.

Tracheal-esophageal puncture procedures have been used since 1980 and are a relatively simple means of voice restoration (41). A small, one-way-valved voice prosthesis is inserted through the TEP tract that is surgically created to maintain patency. Air is then shunted via digital or valve occlusion of the stoma into the esophagus without having esophageal contents enter the TEP. Air then passes through the prosthesis to the cricopharyngeal segment for vibration to produce the voicing component of speech. Early speech success following TEP and voice prosthesis fitting has been reported in almost 90% of cases (42,43). Long-term success is reported at between 93% for patients given primary TEP and 83% for those given secondary procedures (44). Success largely depends on patient selection, and in some cases, success can be enhanced by surgical techniques that can prevent pharyngoesophageal segment spasm (45) such as pharyngeal plexus neurectomy or cricopharyngeal myotomy or botulinum toxin injection. Other factors to consider in patient selection are motivation, intellect, dexterity, eyesight, stoma size and sensitivity, hand hygiene, surgical risk, and cost.

### Fluency

Fluency disorders are characterized by a disruption in the ease and flow of connected speech. The most common and well-known type of fluency disorder is stuttering. Stuttering is a very complex, dynamic, and somewhat controversial disorder in that theories and opinions abound regarding etiology, diagnosis, and treatment. Theories regarding underlying cause include genetic, cognitive, psycholinguistic, neuromuscular, as well as multifactorial. It is generally accepted that primary characteristics of stuttering include blocks (absence of sound), repetitions (of sounds or words), and/or prolonged sounds. Secondary behaviors often observed include struggle (body movement, eye blinks, lip/jaw tremors) and avoidance of sounds, words, conversation partners or environments that trigger the dysfluency. The evaluating clinician must be very cautious with diagnosis for several reasons. One, stuttering resolves in 75% to 90% of small children who begin to stutter. Additionally, there is a spectrum of normal dysfluency that is reactive to environmental pressures but is not consistent with a stuttering diagnosis. Labeling one as a “stutterer” when he or she is within the normal spectrum of behavior can be quite damaging and can lead to exacerbated symptomatology.

Due to high variability of type, severity, response to treatment, and possibly cause, having a standard treatment strategy is nearly impossible. However, common approaches include

environmental modifications, desensitization, fluency-shaping techniques (i.e., easy onset, continuous phonation, auditory/visual feedback), and possibly psychological intervention. One component that is quite consistently included is counseling and support by the speech-language pathologist with the goal of changing the patient’s mindset from anticipating stuttering to anticipating fluency. Goals may vary from absence of stuttering to reducing severity and eliminating avoidance behaviors so as to improve quality and effectiveness of overall communication. It is generally believed that any effective treatment program must also have transference into nonclinical functional environments and maintenance as a goal (46,47).

## LANGUAGE

As described earlier, language is an arbitrary system of signs or symbols used according to prescribed rules to convey meaning within a linguistic community (1). An understanding of the mechanisms responsible for the processing and formulation of language is critical to good rehabilitation practice. Various theories have been developed to define language. Linguistic theory of language attempts to account for the rules and structure of language stored in memory; whereas the psycholinguistic theories of language attempt to account for how language is stored and accessed to produce the various verbal forms such as sounds, words, and phrases and discourse. Additionally, the role of attention is needed and has been studied extensively in language processing (48).

Traditional study of language has focused on specified sites being responsible for specific functions. There are many lines of evidence to support the concept that the left hemisphere plays a crucial role in language processing. Goodglass, in 1993, reported that approximately 95% of cases with aphasia had focal lesions in the left hemisphere (49). The traditional approach to language views damage to the third frontal convolution, Broca’s area, as causing language production problems, whereas damage to the first temporal convolution, Wernicke’s area, is associated with language comprehension. This approach is simplistic; more recent research has proven correlation of neurologic lesion with language function to be much more complex. Contributions from the right hemisphere have been noted to give input regarding prosody and comprehension of complex syntax (50). Additionally, other subcortical structures such as the basal ganglia and thalamus have been identified as having roles in language function (51). For example, thalamic hemorrhage has been reported to affect language to varying degrees, with some individuals having almost normal language performance and others demonstrating marked paraphasias and periods of fluctuating consciousness (52,53). These fluctuations may be related more to the role of the thalamus in arousal and selective attention as prerequisites to communication than to its role in actual deficits of language (52). Although most studies confirm the notion that the symptoms associated with subcortical disease may be transitory, individuals who evidence attention and arousal deficits

beyond the acute stage of illness have diminished ability to learn compensations for their communication failures in spite of nearly normal comprehension skills.

## Aphasia

Aphasia is an acquired disorder of all language modalities, including verbal expression, auditory comprehension, written expression, and reading comprehension. It interferes with the ability to manipulate the meaning (i.e., semantics) or order (i.e., syntax) of words, spoken or written. Three important points to emphasize in this definition include

1. The term *aphasia* implies impairment in both receptive and expressive language modalities. Expression may be more severely involved than reception, and reception can appear grossly intact. If the testing instrument is sensitive to subtle change in language behavior, pathology can be identified in the more intact modality.
2. Aphasia is consistent only with focal disease, usually of the left hemisphere. Aphasic symptoms may be part of a diffuse pathologic condition. However, these patients evidence more than disruptions in their ability to manipulate linguistic symbols, such as disorientation. Prognosis and recovery for this group are markedly different from those who evidence aphasia alone.
3. Although it is well-known that aphasic disturbances are usually a consequence of cortical disease, the identification and classification of more atypical aphasic syndromes are also associated with subcortical infarction and hemorrhage (54).

## Language Characteristics

Verbal expressive characteristics of aphasia include anomia, agrammatism, paragrammatism, or paraphasia or the production of jargon, stereotypic, or echolalic language patterns. Although most aphasics display an overall reduction in word classes available for production, they show particular deficits in the retrieval of nouns (i.e., anomia). Because nouns carry a large part of the meaning during an intended message, the language of the anomic patient is described as “empty” because sentences often lack a subject or referent.

In their attempts to retrieve words, aphasics may make “paraphasic” language errors. When the substitution for the intended word is from the same word class, such as *chair* for *table*, it is a semantic paraphasia. The substitution of like sounds or syllables, such as *flair* for *chair*, is classified as a phonemic paraphasia. A final class of paraphasic error is the neologism. Neologisms are attempts at the target that bear no phonemic or semantic relationship to that target, such as, “I want to brush my plover.” Patients who find word retrieval difficult may also circumlocute, or talk around the intended noun, such as saying, “I wear it on my wrist” instead of *watch*.

Agrammatism is a form of expressive deficit characterized by reliance on nouns and verbs (i.e., content words) to the exclusion of articles, verb auxiliaries, pronouns, and prepositions (i.e., function words). Agrammatic productions often are described as *telegraphic*. Paragrammatic language

is characterized by the misuse, rather than the omission, of grammatical elements.

Individuals who have expressive output that is largely incomprehensible, even though the utterance is well articulated and verbose, may display a form of expressive deficit called jargon. Concentrations of neologisms are called neologistic jargon and may be associated with stereotypes such as “blam, blam, blam” substituted for all attempts at verbalization. A preponderance of unrelated semantic paraphasias is semantic jargon. Finally, some individuals evidence echolalia, typified by the patient echoing back the same utterance he or she has just heard.

Written expression also is impaired in typical aphasia, characterized by letter or word substitutions, omissions, or additions (paraphasias) or errors in syntax. The ability to use gestures as a substitute form of expression can be impaired as well (38).

Table 15-2 provides a summary of the terminology used to describe expressive language deficits in aphasia.

**TABLE 15.2** Summary of the Terminology Used to Describe Expressive Disorders of Aphasia

Term	Definition
Agrammatism	The absence of recognized grammatical elements during speech attempts
Anomia	Difficulty producing nouns
Circumlocution	Attempts at word retrieval end in descriptions or associations related to the word
Echolalia	An accurate repetition of a preceding utterance when repetition is not required
Empty speech	A fluent utterance that lacks substantive parts of language, such as nouns and verbs
Jargon	Mostly incomprehensible but well-articulated language
Neologistic jargon	Mostly incomprehensible, some words are partially recognizable, others are contrived or “new”
Paragrammatism	Misuse of grammatical elements, usually during fluent utterances
Phonemic paraphasia	<i>Flair</i> for <i>chair</i> , also called <i>literal paraphasia</i>
Press for speech	Excessively lengthy, often incomprehensible, well-articulated language
Semantic jargon	A combination of unrelated semantic and phonemic paraphasia, together with recognizable words
Semantic paraphasia	<i>Table</i> for <i>chair</i> , also called <i>nominal paraphasia</i>
Stereotypes	Nonsensical repetition of similar syllables for all communicative attempts, such as <i>dee dee dee</i>
Telegraphic speech	Language similar to a telegram, mostly nouns and verbs

Auditory comprehension characteristics of aphasia include deficits of auditory perception and auditory retention. Auditory misperceptions are characterized by a tendency to confuse words that are similar in either meaning or sound. These confusions create a distorted message resulting in errors of comprehension. Most aphasics will experience more errors in comprehension as the length of the auditory input increases. In general, the speed of auditory input, combined with increased length, leads to errors in auditory retention. In addition, increased sentence length often presupposes a more difficult syntax and vocabulary, combining to make comprehension more liable to error. It has been demonstrated that some aphasics retain more information from the beginning of an utterance, whereas others retain information from the end (55). Evaluation of this aspect of the patient's auditory capacity is especially important if rehabilitation is to succeed. Comprehension of reading material also is impaired. The severity of this impairment often is greater than that of the linguistic deficits in other modalities. However, for some, reading comprehension is a relative strength and can be used to augment or facilitate comprehension of the spoken word by pairing the spoken message with a written message.

### Aphasia: The Classical Descriptions

Historically, there have been many attempts to place pathologic language symptoms into homogeneous groups, permitting reference to specific aphasic subtypes. The Boston classification system standardizes terminology by classifying disorders into those in which expressive skills are predominantly fluent and those in which they are predominantly nonfluent (56). Although such a distinction might be useful clinically, it often can be difficult to make this classification, as in the case of a conduction aphasic (a fluent aphasia) who may have long pauses and expressive struggle (nonfluency) during speech. The eight major types of aphasia in the Boston system include the more common forms of Broca's aphasia, Wernicke's aphasia, anomia, conduction aphasia, and global aphasia, as well as the less frequent transcortical types, transcortical motor and transcortical sensory (Table 15-3). Each of these aphasic syndromes has discrete symptoms and is correlated with a specific localized cortical lesion, some with subcortical extension.

#### Nonfluent Aphasias

##### *Broca's Aphasia*

One of the classic localization theory aphasias, with site of lesion in Broca's area (or area 44), located in the third frontal convolution anterior to the precentral gyrus. Often called "expressive aphasia," this aphasia is characterized by expressive skills more greatly impaired than receptive skills. Agrammatic verbal output is a hallmark symptom, with word retrieval more intact than sentence formulation. Error awareness is often good, making the patient a relatively good communicator, as compared with those with other types of aphasias (57). Repetition is typically poor. Reading and writing also show a range of impairments. AOS frequently accompanies Broca's aphasia.

**TABLE 15.3** Summary of the Boston Classification System of Aphasia

Type	Language Characteristics
<b>Nonfluent</b>	
Broca's	Telegraphic, agrammatic expression often associated with apraxia; good comprehension except on more abstract tasks
Transcortical motor	Limited language output; fair naming; intact repetition; fair comprehension
Global	Severe expressive and receptive reduction in language
Mixed transcortical	Severe reduction in expression and reception; repetition intact
<b>Fluent</b>	
Anomia	Word-finding difficulty without other serious linguistic deficits
Conduction	Phonemic paraphasic errors; good comprehension; fluency in bursts; deficits in repetition of low-probability phrases
Wernicke's	Phonemic and semantic paraphasias; poor comprehension
Transcortical sensory	Fluent neologistic language; poor comprehension; intact repetition

##### *Transcortical Motor Aphasia*

Currently, this type of aphasia is believed to be of a smaller site of lesion, located in the frontal lobe, superior and anterior to Broca's area (57). Language function is similar to those of Broca's aphasia with the exception that repetition is relatively preserved.

##### *Global Aphasia*

Associated with a large left hemisphere lesion, typically including both Broca's and Wernicke's areas. It is considered the most severe aphasia with significant deficits in all language modalities. Often, automatic expressions such as counting or profanity are preserved. Also, frequently these patients can use other modalities, such as facial expression and/or gesture, to communicate basic wants, needs, or feelings (57).

#### Fluent Aphasias

##### *Wernicke's Aphasia*

The other classic localization theory aphasia, Wernicke's aphasia is associated with lesion in the Wernicke's area (area 22), the posterior portion of the superior temporal gyrus (57). Often called "receptive aphasia," this aphasia is characterized by receptive skills being more severe than expressive skills. Patients with this type of aphasia often produce sentences with intact grammar and rhythm of speech but frequent paraphasias of both types and/or frequent neologisms or jargon. Due to poor auditory comprehension, error awareness is also poor, usually making for a less effective communicator than one with Broca's aphasia. Repetition is also impaired.

### ***Transcortical Sensory Aphasia***

Lesion is typically in the inferior temporo-occipital border area. It is similar to Wernicke's aphasia, but repetition is relatively preserved.

### ***Conduction Aphasia***

Thought to be related to subcortical lesions in the arcuate fasciculus, an association tract running beneath the cortex, connecting temporal and parietal lobes and carrying impulses between Wernicke's area and Broca's area. In conduction aphasia, repetition is disproportionately impaired relative to auditory comprehension and verbal expression (57). Verbal output is generally grammatical and fluent but has episodes of halting speech during moments of word retrieval difficulty.

### ***Anomic Aphasia***

It is associated with lesion site of the posterior parietotemporal juncture. It typically is the mildest form of aphasia and is marked by word retrieval difficulties, with syntax and fluency generally intact. Verbal output is characterized by frequent semantic paraphasias or overgeneralizations for the intended words. Comprehension impairment is mild (57).

### **Differentiation from Other Disorders**

Aphasia, particularly in the acute stages, may be difficult to differentiate from other disorders that compromise communication. Accurate differentiation is necessary because each communication disorder requires separate treatment and management approaches. It should be noted that aphasia may occur in conjunction with other syndromes. Below are some disorders that compromise communication but should be differentiated from aphasia.

#### **Agnosia**

Agnosia is the inability to interpret or recognize information when the end organ is intact. For example, a patient with auditory agnosia would have normal audiometric hearing thresholds but cannot interpret speech signals at the cortical level. Hence, auditory comprehension will be severely compromised. Patients with agnosia can be differentiated from those with aphasia because they will be impaired in only one modality. For example, the patient with auditory agnosia who has severe comprehension deficits can read the same words through the intact visual modality.

#### **Dementia**

Dementia is a syndrome of progressive cognitive deterioration that adversely affects the ability to communicate (58). Although specific expressive and receptive language disturbances can present as part of an underlying disease process, the aphasic patient does not show evidence of cognitive deficits in such areas as orientation, judgment, self-care, and visual-perceptual skills. The distinction between those patients with language deficits secondary to aphasia and those with diffuse disease is particularly relevant in rehabilitation because the prognosis for retraining specific skills and developing independence is more favorable for the patient with aphasia alone.

### **Language of Confusion**

Language of confusion is characterized by reduced recognition, reduced understanding of and responsiveness to the environment, faulty memory, unclear thinking, and disorientation (58). It often is associated with head trauma. In contrast to the language disorders of dementia, the prognosis for recovery after traumatic injury is more favorable, and the course is not progressive.

### **Aphasia Assessments**

Tests for aphasia measure the patient's receptive and expressive language capacities by sampling different types of language skills through systematically controlled channels. For example, an examination of reception via the visual input system might begin with a concrete task such as copying or matching and then proceed to more difficult tasks such as reading sentences or paragraphs for comprehension. Tests of expression might range from simple repetition to naming to providing definitions or picture descriptions. Most test batteries currently in use provide a representative sample from which inferences can be made about performance in similar linguistic situations. Although most tests of aphasia do sample linguistic competencies, they are not equipped to measure either the least severe or the most severe disorders. Therefore, the examination will have to be supplemented by other specialized formal and informal measures in selected cases. Additionally, most isolated aphasia test batteries do not depict an individual's functional communication performance. To determine one's overall communicative functional status, additional testing is often required.

Some of the more commonly utilized aphasia assessments include the Western Aphasia Battery-Revised (WAB-R), Boston Diagnostic Aphasia Examination (BDAE) third edition, and the Communication Activities of Daily Living-2 (CADL-2) (56,59,60). Also frequently given is the Boston Naming Test (BNT), which is actually a subtest of the BDAE. To assess reading comprehension in varied contexts, portions of the Reading Comprehension Battery of Aphasia-2 (RCBA-2) are often given (61). It should be noted that these assessments are rarely given in their entirety. Depending on the degree of the patient's impairment and the area of deficit the evaluating clinician deems most informative regarding patient function, specific subtests are selected and administered.

### **Approaches to Treatment**

Aphasia treatment should be patient dependent and maximize communication in actual interactive situations. Aphasics, even those with similar types of lesions, represent a heterogeneous group. Because of this heterogeneity, outcomes of treatment are often unpredictable. In addition to building on the patient's communicative strengths, remediation should be directed toward helping the patient, family, and friends accept and adapt to the person's impairment.

Traditionally, the focus of aphasia treatment has been on the stimulation-facilitation approach, in which the patient and clinician interact within a stimulus-response framework on tasks that are related to deficit areas determined during assessment

(62,63). This restitution approach continues to be common practice. Additionally, the teaching of compensatory strategies to facilitate optimal communication despite the deficits is a second approach. For example, verbal expression may be addressed in a stimulation manner, such as naming of pictured objects. It then may be addressed via compensatory techniques, such as the patient using circumlocution or gestures to communicate the idea of a pictured object, a technique that can then be carried over during episodes of anomia. A third goal of therapy is the education and training of the family members or close loved ones in how to best facilitate communication. Training in communicative interaction must focus on the following:

- Appropriate rates of auditory presentation and the importance of pause times
- Differences between concrete and abstract languages
- Use of redundancy to improve comprehension
- Ways to carry the load of a conversation while still involving the patient
- Utilization of contextual cues to comprehend what the patient may be communicating
- Ways to verify messages from the patient
- Ways to combine gesture and oral languages to facilitate communication
- Allowing the appropriate amount of time for a patient to formulate a response before restimulation (i.e., questioning or repeating)

Environmental controls are also important in aphasia rehabilitation and are similar to environmental language stimulation described by Lubinski (64). The patient's environment should be evaluated to determine how it might be manipulated to enhance communicative skills and compensate for deficits. These manipulations should focus on ways to control distractions, to provide favorable seating and lighting when possible, to control the number of speakers, to suggest the time of day when the patient's performance is best, to control daily situations so that the patient has a need to communicate, and to provide adequate reinforcement for communication. Other environmental controls that enhance communication because they allow for linguistic predictability include the design of a daily regimented schedule and keeping items in the environment such as chairs, utensils, and food items in familiar places. These controls can maximize communicative effectiveness. However, patients who react favorably to such controls should also have them removed at prescribed times, forcing them to practice using their language in reaction to less predictable situations. These encounters, if positive, can lead to significant improvement in communication.

Careful consideration should be made in determining frequency of treatment and reassessment. Some patients, who are early in their recovery phase, are able to sustain good attention and incorporate use of trained techniques and may be good candidates for daily intervention.

In general, patients who evidence diffuse cortical signs in addition to their linguistic deficits, have significant difficulty with sustained attention, and/or are unable to carryover learned

strategies may be more appropriate for less intensive intervention with perhaps a greater focus on family training and suggesting environmental controls. As with the treatment of any disorder, ongoing reassessment is important for modification of treatment plan, and data should be kept on the patient's accuracy and processing time as measures of change.

### Communication Impairment After Right Hemisphere Damage

Communication impairments with right hemisphere-damaged patients largely relate to cognitive skills that impact communication. A cognitive-communication disorder is defined by the American Speech-Language-Hearing Association (65) as a disorder that encompasses difficulty with any aspect of communication that is affected by disruption of cognition (65). Communication may be verbal or nonverbal and includes listening, speaking, gesturing, reading, and writing in all domains of language (phonologic, morphologic, syntactic, semantic, and pragmatic). Cognition includes cognitive processes and systems (e.g., attention, perception, memory, organization, executive function). Areas of function affected by cognitive impairments include behavioral self-regulation, social interaction, activities of daily living, learning and academic performance, and vocational performance (65).

Due to the speech-language pathologist's knowledge about normal and abnormal development, brain-behavior relationships, pathophysiology, and neuropsychological processes as related to the cognitive aspects of communication, American Speech Language Hearing Association (ASHA) states that the Speech-Language Pathologist (SLP) is qualified to assume a habilitative and rehabilitation role in managing cognitive-communication disorders (65). Skills affected by right hemisphere damage include attention, orientation, visual or auditory perceptual skills, memory, social communication (pragmatics), organization, reasoning and problem solving (executive functioning), safety awareness, and judgment. Some patients experience anosognosia, an unawareness of the problems experienced, which makes remediation more challenging (65).

The pragmatic aspects, such as the lack of facial expression while speaking, failure to maintain eye contact, failure to use gesture, and lack of vocal inflection, have all been described in the patient with right hemisphere damage (66). Loss of inflectional patterns that signal anger or frustration is not surprising, given the role the right hemisphere plays in decoding and recalling melodies. The clinician must be alert to the possibility of such a pathologic process because loss of these affective cues often is mistaken for the functional states of rudeness or unconcern for another's feelings.

Additional problems with extraverbal aspects of communication also help to explain the "difficult-to-get-along-with" personality of the patient with right hemisphere damage. Extraverbal skills include behaviors such as appreciation of humor and figurative language and the use of pragmatics such as the ability to maintain a conversational topic and turn-taking during conversation. These patients have difficulty in organizing information, and they fail to make use of contextual cues.

Failure to recognize these cues results in many conversational irrelevancies, as well as poor monitoring of rate and amount of expressive language when they stray from or completely lose the thread of the conversation. Failure to recognize humor and metaphoric language structures may be misunderstood by family members as a noncaring, depressed personality. Problems in interpreting incoming visual and auditory information, long known to be a right hemisphere function, make it difficult for these patients to get the main idea of discourse, leading to further frustration of friends and family.

### Assessment

Before the Rice Evaluation of Communication Problems in Right Hemisphere Dysfunction (67), no formal assessment tool was available for the systematic evaluation of the communication skills of the patient with right hemisphere damage (68). This test offers a rating system for the use of pragmatics, nonverbal skills such as eye contact and facial gestures, interpretation of metaphoric language, memory skills, writing, visual scanning and tracking, and analysis of conversation, including topic maintenance, verbosity, and reference. Approaches to treatment based on the analysis are presented.

Informal assessment tools for communication ability were described by West et al. (69). Their screening battery includes exploration of basic language skills, an analysis of single-word responses to part-whole tasks, oral opposites, written opposites, oral analogies, and printed analogies. Other sections include the interpretation of idioms and proverbs, effects of imagery, and evaluation of the patient's ability to appreciate humor.

Clinicians frequently will gather a variety of subtests from different sources to assess areas of cognitive communication, including attention, memory, executive functioning, and visual-spatial skills. Understanding patient personality and functional status prior to neurologic injury is important; therefore, interview of close friends or family members is a critical element in assessment.

### Treatment

Treatment should concentrate on three broad areas as follows:

1. The communication specialist should develop tasks that help the patient attend to contextual cues in an effort to reduce verbosity and improve topic maintenance, retell stories in a fashion that highlights the main points, and produce language that follows a logical sequence. Although these tasks appear related to the impairment, no data support success or failure using such strategies.
2. Education of the patient's family members on how the loss of pragmatic and affective languages can affect their perception of the patient's personality is important. Rehabilitation successes in other areas will be diminished or lost if the patient's family members do not understand the reasons for the adjustment to a new personality.
3. Many speech-language pathologists also address the cognitive processes that affect communication, such as attention, memory, executive functioning, and safety awareness/judgment. They do this through tasks that are individualized to address

the specific deficit areas and can translate to optimizing function in real-world situations. For example, answering questions regarding a map can address visual attention, visual perceptual skills, left attention, and, depending on the complexity of the map and the questions, executive functions such as planning, problem solving, and reasoning. Even more functional is the actual use of a map to route find within an unfamiliar setting. This will address the aforementioned skills but will more greatly challenge attention, executive functioning, and safety awareness.

### Communication Impairment After Traumatic Brain Injury

Patients with TBI will suffer some degree of cognitive-communication impairment. Those with mild TBI may not initially have symptoms. Instead, difficulties may develop over weeks or months and/or may be subtle and thus may be missed by medical personnel. Such symptoms include memory loss, poor attention/concentration, emotional irritability, easily getting lost or confused, and reduced speed of thinking. The moderate to severe TBI patients will have more evident deficits, usually from the beginning stages. These include

- Attention
- Concentration
- Distractibility
- Memory
- Speed of processing
- Confusion
- Perseveration
- Impulsiveness
- Language processing
- "Executive functions" (70)

The Rancho Los Amigos Scale—Revised is a tool that describes recovery from TBI in terms of increasing arousal and responsiveness, with reducing confusion and inappropriateness. As such progress takes place, improved cognitive communication and language processing also develops. An interval scale from lowest function to highest is the means for scoring and is depicted in the following manner. Levels I, II, and III require total assistance. Level I describes when the patient has no response to any type of stimuli—visual, auditory, proprioceptive, vestibular, or painful. Level II is when generalized responses (such as increased respiratory rate, whole body movements) occur after the presentation of a stimulus. Level III is when localized responses begin to emerge. For example, the patient will turn toward or away from a specific stimulus and may respond inconsistently to simple commands. During level IV, the Confused-Agitated: Maximal Assistance stage, the patient is more alert and engages in simple purposeful behavior (i.e., scratching an itch) but becomes easily agitated. Verbalizations often are incoherent and/or inappropriate, and attention is very brief. During level V, the Confused, Inappropriate Non-Agitated: Maximal Assistance stage, the agitation reduces; however, it can be triggered easily during overstimulation. The person is generally not oriented and is unable to learn new information. Sustained

attention is slightly longer, but goal directed problem-solving or self-monitoring behavior is minimal to absent. Level VI represents the Confused, Appropriate: Moderate Assistance stage, where orientation is inconsistent, attention to highly familiar tasks improves, and ability to use external memory aids with assistance emerges. New declarative learning and awareness of impairment tend to be severely impaired. During level VII, the Automatic, Appropriate: Minimal Assistance for Daily Living Skills stage, carryover of new learning begins and ability to self-monitor and correct errors emerges. Executive functioning and social functioning are impaired, having a significant impact on function in home and community environments. Level VIII is the Purposeful, Appropriate: Stand-By Assistance stage, where one can use assistive memory devices to recall functional information, attend to familiar tasks for at least an hour in distracting settings, learn new tasks, verbalize awareness of deficits but may not appreciate the impact and take appropriate corrective action. Depression or irritability may be present. Level IX is the Purposeful, Appropriate: Stand-By Assistance of Request stage with more independent alternating attention, with heightened self-awareness and executive functioning, and with standby assistance as needed for optimal success in challenging environments. Frustration tolerance may be low. The final level is X, the Purposeful, Appropriate: Modified Independent stage, in which one may be able to multitask with breaks, independently complete tasks requiring high levels of executive functioning with extra time, and/or use compensatory strategies. Social behavior is appropriate. Frustration tolerance may be low when sick or fatigued (71). Recovery through the stages can happen quickly, in a matter of days or weeks, or happen over months. It is important to be constantly reevaluating the patient to determine current skills/deficits and modify treatment plan accordingly.

The most pervasive cognitive-communication deficits with chronic TBI patients include memory, executive function, and social behavior (72). Working memory, the ability to hold and manipulate information in the mind over short periods of time, and declarative memory (e.g., stored facts, memory for past events, and memory for words), one type of long-term memory, are most affected. Implicit, or procedural, memory, which is the other form of long-term memory and includes habits, skills, and emotional associations, typically remains preserved. Executive functions affect focused attention, planning and organizing, problem solving, verbal reasoning, and metacognition. Social functioning includes emotion recognition, social knowledge, social performance, and execution of these integrated functions in real-time interactions (72).

It should be noted that one of the more challenging aspects of rehabilitating individuals with TBI is the frequent presence of poor self-awareness, or insight. The patient often does not recognize or have an appreciation of the consequences of his or her deficits. This poses a safety risk and can impact patient participation in therapy.

### Assessment

The Academy of Neurologic Communication Disorders and Sciences (ANCDS) has recently published practice

guidelines for the assessment of persons with TBI. After review of standardized tests frequently given by speech-language pathologists and/or recommended by test publishers and distributors for assessment of communication ability in persons with TBI, a report was generated delineating best assessment tools with regard to test reliability and validity. These include the American Speech-Language and Hearing Association Functional Assessment of Communication Skills (ASHA-FACS), the Behavior Rating Inventory of Executive Function (BRIEF), the CADL-2, the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS), the Test of Language Competence—Expanded (TLC), and the Western Aphasia Battery (WAB) (60,73–76).

The ANCDS, however, also strongly states that standardized tests are only one component of the evaluation process, which must include multiple sources of information, including the person's preinjury characteristics, stage of development and recovery, and communication-related demands of personally meaningful everyday activities (72). Most clinicians will utilize a combination of formal and informal measures designed to capture the new onset of cognitive-communication deficits. Based on how these deficits impact the individual's function in daily life, an individualized treatment plan will be developed.

It should be noted that assessment remains particularly challenging in the very early stages of recovery. Speech-language pathologists often become involved once the patient has begun to demonstrate some degree of localized response, becoming minimally aware of his or her immediate surroundings. The Western Neuro Sensory Stimulation Profile (WNSSP) can be administered to monitor change in patients in the Rancho Los Amigos Scale (RLAS) II–V stages. This assessment can be repeated often to demonstrate progress toward increased motor and sensory responses. It also provides a structure in which to assess presence of and best method of a yes/no response to basic questions (77).

Once the patient progresses into stage V or VI on the RLAS and has the attention and responsiveness to participate in more formal assessment, then some of the aforementioned tests approved by the ANCDS may become appropriate. However, particularly while the patient remains hospitalized, whether in acute care, acute rehabilitation, or subacute rehabilitation, focus in assessment may continue to be more informal, related to the ability to complete basic functional skills for the hospital environment.

### Treatment

Treatment typically involves tasks that improve orientation and memory, help in developing selective attention and discrimination, and emphasize reasoning, executive functioning, and social functioning.

In early stages of recovery, RLAS II–III, the therapist will focus on elicitation of responses to sensory stimulation with the goal of progressing from generalized to localized to purposeful responses. The challenge to the patient in these stages is to recognize, process, and react to sensory input. Environmental management of distracting stimuli that may overload the patient's senses is important. Next, in RLAS IV–V stages, the

discrimination, organization, and integration of the input become difficult, leading to restlessness and extreme confusion. The goal of treatment in these stages is keeping the patient oriented, improving attention to very basic tasks (card sorting, simple conversation, eating a meal), following simple directions, and developing a trusting relationship that will become particularly important in later stages. The patient usually will begin to speak in these stages. Language of confusion or anomia may be present and should be addressed. Again, managing the environment is also important. Too much stimulation can very much disrupt the integration of sensory input and increase agitation and restlessness. During RLAS VI and VII stages, the focus is on developing memory strategies such as the use of an external memory aid (memory book) to help the patient recall daily activities and important facts. Also addressed is improving attention in tasks of increasing length while controlling for environmental distractors. Executive functioning and social functioning begin to be targeted in these stages, but poor self-awareness can be a limiting factor.

In stages IX and X, the TBI patient is beginning to have the ability to metacognate, and self-awareness is improving. Treatment focus is on the memory, attention, executive functioning, and social functioning skills that the patient requires for returning to community or work environment. Tasks should integrate most or all skills and remain very functional, such as planning a dinner menu to then be executed at home. The patient can report back with analysis regarding successes and challenges. Computer-based therapy is also commonly used, via functional use of the internet or with specific software that addresses attention, memory, and executive functioning.

The ANCDs has reviewed all Class I, II, and III research studies related to cognitive rehabilitation and published evidenced-based practice guidelines with regards to attention, memory, behavioral intervention, problem solving, and self-awareness.

In acute rehabilitation, there are currently no well-controlled studies showing that direct therapy improves outcomes beyond what can be accounted for in spontaneous recovery. However, given that procedural learning remains intact, there is evidence that certain skills and strategies can be learned in this early stage. In the chronic stages, there is good evidence that attention training, intervention for behavioral problems, use of external memory aids, and treatment of problem solving are beneficial in certain contexts.

- Practice guidelines for treatment of attention indicate that individualized attention exercises in at least weekly treatment sessions 1 hour in duration lead to positive outcome measures in tests sensitive to attention and working memory as well as outcome measures that include activity-based self-report (72).
- Practice guidelines related to external memory aids indicate that they do help people with memory problems. Instructional techniques for any new learning, but particularly with use of memory aids, should rely on procedural

learning. This technique is commonly referred to as spaced retrieval training (78) and relies on high amounts of errorless, distributed practice, with prompts faded over time (72,78).

- Practice guidelines for training of self-awareness in young and middle-aged adults indicate that by increasing understanding of the individual's injury and its implications and providing feedback to improve self-awareness, self-monitoring, and self-control of disruptive behaviors in specific contexts, improvement is possible. There is no evidence of generalization; therefore, the treatment needs to be in a context as specific to the target task as possible. Likewise, in young and middle-aged adults, there is evidence that problem solving and behavior disorders can be improved in personally relevant activities (72).

An important role of the speech-language pathologist throughout the continuum of care is family training. How to speak to the patient, utilize external aids, and modify the environment by managing stimulation are all important. Also, how best to intervene to manage disruptive social behavior can be helpful information. Family members are sometimes required to live with someone with a new personality and ability to adapt can be very difficult. Referrals to psychology or social work are often necessary.

## Language Deficits and Dementia

Patients with dementia present with a generalized intellectual impairment that compromises communication efficiency. In general, those patients who are labeled "demented" have acquired memory impairment and other disorders of cognition. The severity of the dementia may correlate with the degree of communication impairment. Wertz characterized the linguistic performance of these patients as a deterioration of capacities in all communication modalities consistent with the deterioration of all other mental functions (79). Because dementia usually results from a progressive, diffuse pathologic process, patients rarely improve, and it is difficult to identify any learning strengths. There is also recent evidence to show that language may be a barometer of change in charting the deterioration in dementia (80). Knowledge of these changes may be useful in family counseling and subsequent management of the communication disorder.

The inability of a demented patient to communicate a message that is relevant, timely, and completely understood by the listener often depends on the severity of the disruption of those cognitive constructs that subserve language, such as general orientation, attention, memory, and visual-perceptive integration. Although some patients in the early stages of dementia complain of an inability to produce nouns as their major communication deficit, this is not a consistent finding in all patients. Most sensitive to linguistic compromise is the patient's ability to name items in a category of either semantically or letter-related items (81). Progressive deterioration of memory skills particularly coincides with interruptions in normal communicative discourse. Inability to monitor (i.e., identify, sort, remember, or integrate) auditory

or visual messages, as well as verbal and graphic output, may result in a paucity of information, problems in topic cohesion or relevance, indefinite phrases, and perseveration of words and ideas. Overuse of stock phrases, lack of conversational initiation, and echolalia are more common in frontotemporal dementia such as Pick's disease (82). Those with Alzheimer's dementia may be more fluent than those with frontotemporal dementia throughout the course of the disease. However, sentences may be incomplete, marked by paraphasia and evidenced by obvious word-finding errors. Comprehension difficulty is more pronounced in Alzheimer's disease, especially for tasks involving the decoding of complex syntax. Reading may remain intact in frontotemporal dementia but is typically poor in those with Alzheimer's dementia. These deficits of language will interfere with most communicative exchanges. Only those interactions that are at the concrete and nonpropositional level will be successful. As the severity of dementia progresses, syntax and phonology may be preserved until the final stages. Discourse is characteristically neologistic and echolalic at this stage, and so repetition may be spared, but comprehension will be lacking. In the most severe cases, meaningful communication is absent, and the patient may be mute.

### Assessment

Assessment of linguistic skills usually is informal but should be accomplished at regular intervals to chart progression. Obler suggests the following categories for evaluation: orientation, naming (i.e., confrontation and responsive), analysis of discourse, comprehension, repetition, verbal fluency, idioms and proverbs, sentence construction, number facts, automatic speech, and reading and writing (83). Tests of memory, because of its close relationship to linguistic ability, also need to be administered at regular intervals. The Dementia Rating Scale (84), although not specific to communication, is a psychometrically sound tool used to assess general deficits of cognition. The five subscales assessed include attention, initiation and perseveration, construction, conceptualization, and memory. The impact of memory on linguistic communication can be measured by the Arizona Battery for Communication Disorders of Dementia (85). The test is comprised of 16 subtests, four of which—story retelling, delayed; word learning, free recall; word learning, total recall; and word learning, recognition—can be used as a screening tool to help differentiate the linguistic communicative deficits of patients with Alzheimer's disease from those with normal skills.

### Treatment

Treatment for patients with communication disorders secondary to dementia should be supportive. Treatment goals should include environmental controls, capitalization on the preserved procedural memory, and family education. Environmental structure provides orientation and reinforces memory that, in turn, will improve the accuracy of linguistic attempts. Interactions with the patient should be structured to reduce demands beyond the limits of the cognitive system as

established by psychometric evaluation. Frequent measures of linguistic function are part of the treatment and are necessary so that family and friends can be informed about how much to expect from the patient both receptively and expressively. This knowledge will reduce frustration for the patient and family. Some patients retain skills longer than others do, and knowledge of the best input and expected output modalities is useful in management. Because dementia often results in diminution of all linguistic modalities, performance may be strengthened through the use of multiple channels such as the combination of gestural, written, and verbal language. This multimodality strategy is a process that should be taught to family members.

Recent evidence suggests that combining exercise activities with cognitive stimulation tasks may facilitate the communicative process (86). This may be related either to increased blood flow to the brain during periods of aerobic exercise or to stress management. Therapy to enhance communicative skills applied during rest periods from aerobic exercise also may be of importance for patients with dementia (87). Although the evidence that certain medications facilitate memory in patients with dementia remains controversial, no data are available to support the use of facilitative drugs to enhance language.

## SWALLOWING IMPAIRMENT

Swallowing is an essential life function that begins *in utero*. It is necessary to survival both because it is the source of hydration and alimentation and because it has a crucial role in maintaining airway integrity by clearing residue from the oral cavity and pharyngeal tract. Abnormal swallowing (dysphagia) may lead to dehydration, starvation, aspiration pneumonia, airway obstruction, and—in the worst cases—death. Dysphagia is frequently associated with cerebrovascular disease, TBI, head and neck cancer, and other conditions common in rehabilitation patients. In many cases, swallowing impairments are amenable to rehabilitation treatment.

## PHYSIOLOGY OF SWALLOWING

Swallowing is coordinated with other patterned behaviors, including respiration and mastication. Swallowing is divided into several phases in an effort to simplify description. The phases (i.e., oral preparatory, oral propulsive, pharyngeal, and esophageal) are based on anatomic location and flow of the bolus (88–91). These phases are neither discrete nor isolated from each other and may overlap in time. Events in one phase may impact events in another phase or in multiple phases, ultimately affecting the physiology of the whole swallow.

### Anticipation Before the Swallow

The concept of anticipation is a relatively new construct in the physiology of swallowing. This includes the perception and cognition regarding nutritional materials prior to introduction

to the mouth. Specifics include the size of the bolus prepared for intake, the fine motor control for placing the bolus on a fork or spoon or sipping from a straw or cup, instructions for feeding, and the speed at which food or drink is presented to the mouth, all of which can affect the physiology of eating, drinking, and swallowing. Some investigators have proposed calling this an Anticipatory Phase of swallowing (89,90,92–94).

### Oral Preparatory Phase

The oral preparatory phase is a necessary step prior to the initiation of the oropharyngeal swallow. The manner in which the bolus is prepared for swallowing varies, depending on the consistency of the material. The preparation for solid food entails several distinct but overlapping processes. Ingestion occurs first and then passage of food through the lips and into the mouth by biting or manual placement. This is followed immediately by stage I transport, in which food is propelled from the anterior to the posterior oral cavity. If food particles are still too large or coarse for swallowing, they remain in the mouth. During mastication, food is softened, and food particles are reduced in size by chewing (i.e., incising, crushing, and grinding) and mixing with saliva. Food in the mouth stimulates mechanoreceptors for the trigeminal nerve (cranial nerve V) located in the periodontal membrane and palate. Stimulation of these receptors activates the central pattern generator for mastication, producing sequential contraction and relaxation of the elevator and depressor muscles of the mandible and resulting in cyclic opening and closing of the mouth. This cyclic grinding motion of the jaws is coordinated with rotation of the tongue, pushing the food between the upper and lower teeth. Saliva is excreted from the salivary glands, helping to break down the food and stimulate the taste buds. The physical consistency of the food is monitored continuously by oral mechanoreceptors. Liquids can be held either between the tongue and palate or in the lingual sulcus, or the oral propulsive phase is initiated immediately on ingestion. Soft foods can be held immediately between the tongue and anterior hard palate or lateralized for mastication before resuming a midline position for swallowing.

### Oral Propulsive Phase

The oral propulsive phase begins once the bolus has been prepared and is ready for transport posteriorly into the pharynx. Once a small portion of solid food is fully prepared (tritured), a cycle of stage II transport is initiated. The tongue pushes upward and forward in the mouth, contacting the anterior portion of the hard palate. The area of tongue-palate contact expands backward, propelling the small portion of the tritured food through the faucial arches and into the pharynx. A small portion of food may remain in the oropharynx while chewing continues for several more jaw cycles. Additional small portions of tritured food may be propelled into the pharynx multiple times, depending on the bolus size (95). When a large enough bolus has been prepared, a swallow is initiated. The pharyngeal phase of swallowing follows immediately. With liquids, the mechanism for transport to the pharynx is as

described for solid foods, but the onset of the pharyngeal phase is more rapid after oral propulsion.

### Pharyngeal Phase

When appropriate sensory input reaches the medullary central pattern generator for swallowing, a complex motor sequence is elicited to propel a bolus through the pharynx, around the larynx, through the upper esophageal sphincter (UES) containing the cricopharyngeus, and into the esophagus, all within a duration of approximately 1 second in healthy adult humans.

When the pharyngeal phase is initiated, respiration ceases and the palatopharyngeal isthmus closes to seal off the nasopharynx, preventing entry of the bolus into the nasal cavity. The larynx closes by adduction of the vocal folds and anterior tilting of the arytenoid cartilages to meet the epiglottic petiole. At nearly the same time, the hyoid bone is elevated and pulled forward by the suprahyoid muscles. In turn, the hyoid bone and supralaryngeal muscles pull the larynx superiorly and anteriorly. The cricopharyngeus muscle relaxes, becoming compliant and allowing the UES to open (96). Opening of the UES is essential to the pharyngeal phase. Relaxation of the cricopharyngeus is permissive, but the primary force for UES opening is the anterior traction of the hyolaryngeal complex provided by the submental muscles. The tongue moves backward and downward, pushing the bolus through the pharynx like a plunger. The epiglottis inverts, deflecting the bolus around the larynx and away from the airway. The pharyngeal constrictors contract sequentially with a peristaltic wave from top to bottom, clearing the pharynx of residue, following the tongue's downward motion. Following the passage of the bolus into the esophagus, the larynx opens, the UES closes, and the cricopharyngeus muscle resumes its tonic contraction, sealing the UES (67,97,98).

### Esophageal Phase

The wave of pharyngeal constriction that cleared the bolus into the esophagus continues throughout the esophagus as a primary peristaltic wave that propels the bolus through the lower esophageal sphincter (LES) and into the stomach. Esophageal clearance is assisted by gravity but also requires relaxation of the LES. Reflux of stomach contents is prevented by tonic contraction of the LES and reflex esophageal swallowing that is triggered by esophageal distension (secondary peristalsis).

### Evaluation of Swallowing

When a complaint about swallowing is registered or dysphagia is recognized, an evaluation is required with two primary goals in the clinician's mind: (a) to maintain patient safety during nutritional intake and (b) to determine the best manner for patients to obtain adequate nutrition while maintaining patient safety (99,100). Such an evaluation should consist of a detailed description of the complaint, complete medical history, and a physical examination of the peripheral deglutitory motor and sensory system, including trial swallows under observation. Instrumental diagnostic studies, including videofluorography, manometry, electromyography, and fiberoptic endoscopy, are indicated in selected cases.

### Description of the Complaint

In many instances, the subjective complaint gives the examiner clues to the cause of the swallowing problem. Critical data include a sensation of food sticking in the throat or chest, difficulty initiating swallowing, occurrence of coughing or choking spells associated with eating, drooling or difficulty clearing oral secretions, weight loss, change in diet or eating habits, episodes of aspiration pneumonia, and symptoms referable to gastroesophageal reflux. Difficulties swallowing solids and liquids should be contrasted and compared.

With liquids, patients may complain of coughing or choking during drinking. These symptoms are suggestive of laryngeal penetration (entrance of the bolus into the larynx but remaining above the level of the vocal folds) and/or aspiration (passage of the bolus through the vocal folds and into the lower airway) and should be taken seriously. Aspiration is common in patients with swallowing disorders and can lead to serious medical complications. For example, between 8,000 and 12,000 Americans choke to death each year, many with undiagnosed swallowing disorders (101,102). Aspiration of tiny amounts is normal, and the response to aspiration varies widely. It is clear, however, that aspiration in patients with dysphagia significantly increases the risk of pneumonia, so its detection is critically important (103–109).

A complaint of food sticking in the throat or chest is common with solid food and raises the possibility of food pathway obstruction. It may have many causes, however, including bulbar palsy, pharyngoesophageal diverticula, tumor, stricture, or esophageal dysmotility. The sensation of food sticking in the chest (thoracic dysphagia) is usually associated with disease of the esophagus or LES. A complaint of cervical dysphagia (food sticking in the neck), however, has poor localizing value and may be caused by dysfunction of the pharynx, esophagus, or either esophageal sphincter. Nasal regurgitation is associated with weakness or incompetence of the palatopharyngeal mechanism. Oral malodor is associated with tumor, infection, mastication problems, poor oral hygiene, or pharyngeal retention of food and can suggest the presence of a diverticulum of the pharynx or esophagus. Odynophagia is a worrisome symptom, often associated with cancer of the esophagus. Heartburn, acid or sour regurgitation, and regurgitation of digested food suggest gastroesophageal reflux disease. Reflux or vomiting of stomach contents can lead to respiratory complications such as aspiration pneumonitis. Instances of aspiration pneumonia can be indicative of severe dysphagia. The same anatomic and neuromuscular systems are shared by voice, speech, and swallowing, so dysfunction in any of these systems should be carefully noted and described. Weight loss or changes in eating habits often reflect an underlying problem with swallowing as well.

### History

Data should be compiled from a review of the patient's general health and social histories, including what led to the complaint of dysphagia. Attention should be paid to the neurologic history that might suggest contributing factors such as stroke, head trauma, neuromuscular disorders, or degenerative diseases

(parkinsonism, multiple sclerosis, dementia) any of which can cause dysphagia. Respiratory disorders and use of artificial airways can also contribute to dysphagia. All prior operations should be noted, especially those involving the head and neck. Current prescription and nonprescription medications should be listed. Those that have side effects of sedation, muscle weakness, drying of mucous membranes, disorientation, or dyskinesia may contribute to dysphagia. Anticholinergic and psychoactive medications are specially noted. Imaging studies are useful for understanding structural changes of the airway and food pathway as well as the brain. Relevant laboratory studies may include important evidence for infection, nutritional deficiency (especially iron deficiency, which may cause esophageal webs), connective tissue disease, or muscle inflammation. Current diet, route of alimentation and hydration, oral health, and disorders affecting behavior or level of consciousness are important to dysphagia rehabilitation.

Psychosocial factors may have a significant impact on swallowing, especially for elderly individuals. An individual living alone may be unable to obtain supervision during meals. For a nursing home resident, prescribing a special diet may be unrealistic. Swallowing must also be considered in the context of feeding. Feeding dependency is an enormous problem for the elderly. Problems with feeding may be difficult to differentiate from impairments of swallowing *per se* (110).

### Clinical Examination and Bedside Swallow Evaluation

#### Clinical Examination

A general physical examination is essential to look for evidence of cardiopulmonary, gastrointestinal, neurologic, and/or metabolic disease that may impair swallowing. This exam includes an assessment of mental status, including the patient's ability to follow directions, and a determination of his or her willingness to participate in therapy. Simply talking with a patient can reveal disorders of voice (dysphonia), speech (dysarthria, apraxia), and/or spoken or written language (aphasia), in addition to cognitive deficits in the areas of orientation, memory, reasoning, and visual-motor-perceptual function (111). A quick, informal screening for these functions provides useful information. Cranial nerves should be assessed carefully. The respiratory system is examined for signs of obstruction or restriction such as tachypnea, stridor, use of accessory muscles (such as clavicular breathing), paradoxical motion of the chest wall, or labored breathing. The head and neck are inspected for abnormal tissue (e.g., discoloration, appearance changes in tissue) and palpated for structural lesions. The hyoid bone and laryngeal cartilages are palpated carefully and gently mobilized. Facial sensation is checked bilaterally. The muscles of the face, mouth, and neck are examined beginning with the muscles of facial expression, carefully comparing movement of the two sides of the face for signs of asymmetric weakness. The masseter and temporalis muscles are palpated as the patient bites and chews. Movements of the lower jaw are assessed in three directions of movement, observing and noting any clicking of temporomandibular joint, pain, weakness, and/or asymmetry. The

examination proceeds to inspection of the intraoral mucosa. Careful attention should be paid to the presence of lesions, changes in tissue color, oral debris, abnormal movement, and dryness. Palpation with gloved hand on the floor of the mouth, gum lines, tonsillar fossa, and tongue serves to help rule out neoplastic growth. Tongue strength can be assessed by placing fingers against the outer cheek and resisting the patient's tongue as it is pushed into the inner cheek. Atrophy, weakness, and fasciculations of the tongue should be noted. The palate is inspected for symmetry at rest and during phonation and gagging. Each side of the pharynx is stimulated to elicit gag reflexes, observing whether the soft palate and pharyngeal walls contract briskly and symmetrically. However, gag reflexes may be difficult to elicit in some normal individuals. The presence of a gag is by no means indicative of a normal swallow, nor is the absence of a gag indicative of dysphagia (112,113). The presence of primitive reflexes associated with chewing and swallowing (such as the sucking, biting, or snout reflexes) should be noted. These pathologic reflexes are often found in patients with damage to both cerebral hemispheres and can indicate impairments of oral motor control.

### ***Bedside Swallowing Evaluation***

The bedside swallowing evaluation (BSE) is a screening examination that includes observing the patient eating and drinking (99,99a). The purpose of a BSE is to determine whether a patient exhibits signs and symptoms of dysphagia or aspiration and whether the patient is appropriate for instrumental examination or further clinical assessment. The BSE is not a "pass/fail" test; rather, it helps determine the next step in a patient's evaluation and treatment.

Trial swallows are an essential portion of the evaluation, but they do carry the risk of aspiration. A risk-benefit ratio for the BSE should be considered for each patient. The BSE is the safest when the patient is able to generate a voluntary or reflex cough and is able to follow simple commands. Unstable respiratory status is a relative contraindication. If the determination is made to proceed with a BSE, we recommend using a substance that is relatively safe if aspirated. Clear water and/or small ice chips are relatively innocuous for screening trials at the bedside. Upon presentation of small volumes (1/4 to 1 teaspoon of water/ice chips), the examiner observes and palpates the neck as a gross measure for the promptness of the swallow and adequacy of laryngeal elevation. Clinical signs and symptoms of overt aspiration include coughing, choking, gurgling, wet or hoarse vocal quality, throat clearing, and stridor following the swallow. More subtle signs of aspiration include teary eyes or sniffing. Other clinical observations include drooling, expectoration of food/liquid, a slow rate of eating, residual food in the mouth after swallowing, impulsive eating or drinking, and abnormal posturing of the head and neck with swallowing. The absence of these overt clinical signs or symptoms *does not* necessarily mean that there is no aspiration. Silent aspiration (i.e., aspiration in the absence of overt signs or symptoms) is common and a high index of suspicion is imperative (108,114–118).

A half teaspoon of crushed ice may elicit chewing because of its texture and temperature. The examiner can observe the chewing action and feel for the laryngeal elevation to indicate that a swallow has occurred. Once it has been determined that the patient adequately elevates the larynx and that there is an adequate protective cough, other substances with varying textures and consistencies can be tried, again considering the risk-benefit ratio mentioned earlier. Soft, solid foods will also elicit chewing and allow the examiner to observe oral coordination and feel for laryngeal elevation. The mouth should be inspected for retention of food after swallowing. The BSE also presents an opportunity to assess the patient's ability to perform compensatory maneuvers, such as neck flexion or breath holding, that can be later assessed during an instrumental examination.

The purposes of the history and physical examination are to observe actions of the swallowing mechanism, to characterize the nature and severity of the swallowing deficit, to screen the patient's ability to perform compensatory maneuvers, and to determine whether instrumental examination(s) are necessary. The physical examination is neither sensitive nor specific for identifying aspiration and cannot prove or disprove that a patient aspirates (119). In this regard, any suspicion of difficulty should be immediately referred for further evaluation.

### ***Diagnostic Studies***

Similar to a BSE, the instrumental examination of swallowing is not a "pass/fail" test. The purpose of instrumental examination is to determine the mechanism of swallowing dysfunction while maintaining a safe method for alimentation and hydration. Additional goals include detection of structural defects, determining which physiologic components (e.g., bolus preparation, tongue control, initiation of the pharyngeal swallow, tongue base retraction, laryngeal closure, UES opening, esophageal clearance) are impaired, detecting the presence of and mechanism for aspiration, and testing of therapeutic and compensatory techniques based on the physiologic impairments that are recognized. Indications for instrumental examination include frequent choking episodes, difficulty managing secretions, wet vocal quality after a swallow, respiratory complications, and unexplained weight loss. Relative contraindications include inability to cooperate with the examination and severe respiratory dysfunction. Two methods are discussed in some detail below—the videofluorographic swallowing study (VFSS) and the fiberoptic endoscopic swallow study.

### ***Videofluorography***

The VFSS, sometimes referred to as a modified barium swallow study, is considered the gold standard for evaluation of oral or pharyngeal dysphagia. This evaluation is not to be confused with a routine clinical barium swallow or barium esophagram (evaluation of the esophagus). The rehabilitation approach to videofluorography is to have the patient swallow radiopaque liquids and solid food with varying consistencies toward the goals of detecting abnormalities of the swallowing mechanism while establishing a safe and efficient method of

eating and drinking. An empirical approach is used to identify the factors associated with safe and unsafe swallowing such as the consistency of liquids/food, volume of liquids/food, posture of the patient (especially position of the head and neck), and the means for presenting the food. When abnormalities of swallowing (such as aspiration or retention in the pharynx after swallowing) are recognized, compensatory techniques (such as alteration of bolus consistency or posture, or respiratory maneuvers) are attempted and their effectiveness tested empirically (91,120).

Limitations of the VFSS include concerns for radiation exposure and need to modify food consistency with barium. Advantages include viewing the entire swallow from the oral cavity to the esophagus (even to the stomach); viewing aspiration before, during, and after the swallow; and viewing the physiologic effects of rehabilitation techniques in detail. These advantages are unique to VFSS and make it an invaluable tool for assessment of dysphagia. Risks of the VFSS are minimal in comparison to its benefits.

A complete VFSS examination begins with a small amount of thin liquid barium. Both lateral and anterior-posterior views should be obtained with the patient in an upright posture, either standing or seated, depending on posture and physical ability. The oral and pharyngeal stages of swallowing should be studied with the camera focused anteriorly on the lips, superiorly on the hard palate, posteriorly on the cervical spine, and inferiorly on the cervical esophagus. A variety of textures, including thin and thick liquid barium, pudding consistency (barium mixed with pudding), and cookie, are used during the examination. Because concomitant disorders of the pharynx and esophagus are frequent, the examination should include views of the esophagus whenever possible. The esophagus and gastroesophageal junction can be visualized with the patient in an upright, anterior-posterior position, but esophageal function is best assessed in the recumbent position. Many clinicians prefer to separate the evaluation of esophageal function (barium esophagram) from the VFSS, but this requires performance of an additional radiological procedure. Although static x-ray films may be valuable to detect morphologic changes in the pharynx or esophagus, they are not useful in studying the dynamics of swallowing.

### ***Fiberoptic Endoscopic Examination***

A second instrumental evaluation, fiberoptic endoscopic examination of swallowing (FEES), was first described by Langmore et al. (121,122). This method is a practical means for evaluating swallowing when a patient cannot tolerate transport to radiology (e.g., due to critical illness) or is too large to fit in the fluoroscopy system. FEES carries the added benefit of directly visualizing the pharynx and larynx, to inspect for mucosal lesions or motion impairment of the vocal folds. FEES can detect aspiration in patients for whom radiographic studies are difficult, but it should be noted that aspiration *during* a swallow cannot be directly visualized. Furthermore, the FEES does not provide views of the esophagus or its sphincters. This limits its applicability for assessing the anatomy and physiology of

dysfunctional swallowing. Risks of FEES include patient discomfort, bleeding from passage of the endoscope through the nares, gagging, laryngospasm, and vasovagal response. Despite these limitations, FEES is the instrument of choice for visualization of vocal fold closure, medial and anterior arytenoid movement, amount and location of secretions, and anatomical defects of the pharynx and larynx (123).

### **Other Diagnostic Studies**

Esophagoscopy is essential for detecting a variety of esophageal and LES disorders and provides the opportunity for diagnostic biopsy. Electrodiagnostic studies may be helpful for detecting motor unit dysfunction of the larynx, pharynx, and oral musculature but cannot substitute for VFSS (124). Manometry of the esophagus is used to identify and differentiate esophageal motor disorders.

## **MANAGEMENT OF SWALLOWING IMPAIRMENT**

Once the patient's swallowing has been described, the impairment(s) identified, and the compensatory strengths recognized, recommendations for management are generated. The recommendations will include diet, route of alimentation and hydration (i.e., oral or nonoral), the need for compensatory strategies (e.g., special postures, respiratory maneuvers), and the need for therapy, including therapeutic exercises. Additionally, the swallowing clinician may make recommendations regarding medication administration (e.g., with liquid, crushing in applesauce or pudding, or via a feeding tube). When oral feeding is recommended, a plan is needed that will maintain optimum alimentation and hydration intake while minimizing risk of choking, aspiration, and malnutrition. The plan must be individualized and based on an understanding of the patient's swallowing mechanism, the etiology of the dysphagia, and the prognosis for recovery (100). Following recommendations and implementation of the clinical plan, the patient should be monitored for continued signs and symptoms of dysphagia, evidence of pneumonia (fever, cough, and dyspnea), nutritional status (including hydration), and alteration in cognition or mood (125). Table 15-4 lists some of the therapeutic and compensatory techniques that can be employed for patients with oral-pharyngeal forms of dysphagia.

## **HEARING**

Hearing loss is the most common type of acquired sensory impairment affecting between 29 and 36 million adults in the United States (126,127). Following stroke and arthritis, hearing loss is the third most prevalent major chronic disability reported by the elderly (128). The prevalence of hearing loss increases substantially with age. Approximately 18% of American adults aged 45 to 64 years report hearing loss.

**TABLE 15.4** Therapeutic and Compensatory Techniques for Managing Patients with Dysphagia

Technique	Physiologic Swallowing Impairment	Purpose
Effortful/hard swallow	Reduced tongue base retraction, pharyngeal weakness	Improve bolus flow through the pharynx by improving tongue base-to-pharyngeal wall contact
Chin down/chin tuck	Delayed initiation of the pharyngeal swallow	Prevent advancement of the bolus beyond the valleculae
Head turn	Tongue base retraction Pharyngeal weakness	Reduce distance of tongue base-to-pharyngeal wall contact Head is typically turned to the weak side in an effort to direct the bolus to the stronger side of the pharynx allowing for better clearance of the bolus
Head tilt	Oral weakness, reduced sensation	Head is tilted toward the stronger/more sensate side to improve oral control of the bolus
Supraglottic swallow	Impaired/delayed vocal fold closure	Improve vocal fold closure to prevent aspiration
Super-supraglottic swallow	Impaired/reduced vocal fold and laryngeal closure	Improve vocal fold closure and arytenoids-to-epiglottic petiole contact to improve airway closure during the swallow
Thickened liquids	Bolus control	Improve bolus control by slowing the bolus
Thin liquids	Tight UES	Reduce friction, improve bolus passage to esophagus

This rises to 30% in those aged 65 to 74 years old and 47% for those aged 75 years or older (127). With increasing life expectancy as well as increasing noise exposure, the prevalence of hearing loss is anticipated to become even greater in the upcoming decades. Hearing loss is a potentially disabling disorder that can affect communication with a resultant decline in psychosocial functioning, health related quality of life, work productivity, and overall quality of life (129). Hearing loss is frequently unrecognized, misunderstood, and all too often neglected, both by those who are affected and by health care providers.

### Psychosocial Implications of Hearing Loss

The psychosocial impact of hearing loss is poorly understood and under appreciated by most people. Indeed, even those who live with a person with hearing impairment rarely grasp the full extent to which this all-pervasive, invisible disability affects daily living. Until hearing loss is experienced directly or unless a very close acquaintance has impaired hearing, the ways in which a person depends on hearing remain largely unrecognized. Most aspects of daily life are affected by hearing loss in some way. Hearing loss impairs communication, often subtly at first, and increasingly so as the magnitude of the hearing loss increases. In addition, hearing loss restricts environmental awareness and can be a safety concern when it affects the ability to hear warning signals such as sirens and alarms. Hearing loss impacts relationships, employment opportunities, academics, and learning.

The two most commonly reported consequences of hearing loss are depression and social isolation. In addition, adverse effects on general well-being and on physical, cognitive, emotional, behavioral, and social functions have been reported. Social and emotional handicaps are present even in those with only mild to moderate hearing loss. Inability to hear all or part of a conversation may create frustration, anger, and even paranoia. Over time, social connectivity and

relationships may deteriorate, leaving the individual with hearing impairment in isolation and with a diminished quality of life. Hearing loss is associated with reduced abilities to perform activities of daily living as well as instrumental activities of daily living (129).

Misunderstanding and lack of sympathy for the hearing-impaired person seems to be built into our social bias. These attitudes are certainly quite different from our perceptions and treatment of blindness. Often the symptoms of hearing loss (e.g., not answering when spoken to, answering inappropriately, or requiring repetition) encourage other people to talk to and treat the person with hearing impairment as if his or her cognitive abilities were also diminished. This often leads to frustrating or truncated communication attempts.

A major goal of the health care practitioner is to help patients maintain or regain function. The capacity for independent living requires maintenance of functional health. Functional health refers not only to physical health but also to emotional, cognitive, and social health. Physicians are in an excellent position to identify treatable conditions that may compromise their patients' functional performance. Unfortunately, many health care professionals tend to view hearing loss as a benign problem that does not threaten functional health. Regular hearing assessments and management for persons aged 60 years and older should be considered a standard of care.

### Anatomy and Physiology of the Ear

Anatomically, the ear is a complex organ, capable of transforming airborne sound waves into mechanical energy. This mechanical energy is then converted into electrochemical signals and then into neural impulses that are processed as auditory information. The peripheral portion of the auditory system is divided into three sections: the outer, middle, and inner ear. The outer ear is comprised of the auricle (pinna) and the external auditory canal. The auricle is a skin-covered cartilaginous structure and is the most visible portion of the outer ear. The

2.5- to 3-cm long external auditory canal provides an S-shaped tubal channel from the auricle leading to the tympanic membrane. The conical-shaped, approximately 9 mm, tympanic membrane separates the outer and middle ears. The middle ear is an air-filled space containing the ossicular chain (malleus, incus, and stapes) that links the tympanic membrane to the inner ear. The last bone in this chain, the stapes, is the smallest bone in the body. It rests in the membranous oval window of the inner ear. The inner ear is divided into two primary components: the cochlea and vestibular labyrinth. The inner ear is responsible for sensorineural hearing (cochlea) and responding to linear and angular acceleration (vestibule/semicircular canals). The cochlea is a 32-mm long coil-shaped bony structure that contains three fluid-filled membranous cavities, the scala vestibuli, scala tympani, and scala media. Located within the scala media is the organ of Corti, the end organ for hearing, which has approximately 16,000 outer and inner hair cells that are the primary auditory receptors. Located at the top of the outer and inner hair cells are hairlike projections called stereocilia. At the base of the hair cells are approximately 30,000 sensory nerve fibers that project medially through the internal auditory canal, forming the cochlear branch of the eighth cranial nerve. These synapse at the ipsilateral cochlear nucleus located in the cerebellopontine angle at the junction of the pons, cerebellum, and medulla. This begins the central portion of the auditory system. Most auditory pathway fibers from the cochlear nucleus project via the trapezoid bodies to the superior olivary complex and then by way of the lateral lemniscus to the inferior colliculi. The next major synapse of the auditory tracts is at the medial geniculate bodies in the thalamus. From this point, fibers radiate to the primary auditory cortex located at Heschl's gyrus on the sylvian fissure in the temporal lobe.

Physiologic function of the ear is precise and intricate. The outer ear collects airborne sound pressure waves and funnels them through the external ear canal to the tympanic membrane. These pressure waves cause the tympanic membrane to vibrate, at which point the airborne signal is changed into mechanical vibrations that are transmitted along the ossicular chain, first to the malleus, then the incus, and finally the stapes. As the stapes moves, there is vibratory displacement of the oval window, which sends fluid waves along the length of the cochlea. Transduction of this fluid-based mechanical energy into electrochemical neural potentials takes place in the organ of Corti. The complex mechanics of the organ of Corti result in shearing of the stereocilia projecting from the hair cells. As a result, electrochemical events occur within the hair cells that result in release of neurochemical transmitters at the base of the hair cells. Resultant neural impulses are then transmitted via the eighth cranial nerve to the auditory centers of the brainstem and the brain.

### **Assessment of Auditory Function**

#### **Audiologic Evaluation**

When a patient presents with a hearing complaint, diagnosis of the type and degree of hearing loss and the underlying etiology is typically the first goal in the assessment and

management process. This begins with a detailed hearing history that includes questions about the duration of the hearing loss, whether the onset was sudden or gradual, and whether it is stable, progressive, or fluctuant. The patient should be queried about associated symptoms such as tinnitus, dizziness, ear pain or drainage, and aural fullness. In addition, questioning should review family history of hearing loss, as well as loud noise exposure, head trauma, ear surgery, and ototoxic drug use. The physical examination should include an otoscopic evaluation to ensure that the external ear canal is healthy and unobstructed and that the tympanic membrane is translucent and intact. The status of the patient's hearing is determined through a series of audiologic tests. Based on the results of the audiologic examination, the patient's history, and physical examination findings, additional audiologic assessments as well as associated neurologic, laboratory, and imaging studies may be indicated. Only after the assessment has been completed and a diagnosis has been established should rehabilitation of the hearing loss be initiated.

### **Behavioral Hearing Assessment**

#### **Pure-Tone Audiometry**

Determination of pure-tone thresholds across a wide frequency range for air conduction and bone conduction stimuli is the most basic component of the hearing test. Threshold is defined as the lowest level at which a person can detect an auditory stimulus 50% of the time. This information is used to establish the type, degree, and configuration of the hearing loss. Air conduction thresholds are determined in octave, and sometimes interoctave, intervals over the frequency range of 250 through 8,000 Hz. Air conduction signals are presented via supra-aural or insert earphones, and the signal is transferred along the entire auditory pathway, including the outer ear, middle ear, and inner ear. Bone conduction thresholds are established for octave intervals between 250 and 4,000 Hz. For bone conduction measures, a bone oscillator is typically placed on the mastoid prominence of the test ear, while masking sounds are delivered to the nontest ear. The bone conduction oscillator causes the skull to vibrate resulting in direct stimulation of the cochlea, with minimal contribution of the outer and middle ears. Bone conduction thresholds reflect an individual's sensory hearing ability and are unencumbered by disorders affecting the outer and/or middle ear.

Pure-tone thresholds are represented graphically on an audiogram (Fig. 15-1) or in a tabular form. The frequency scale along the abscissa is measured in Hertz (Hz) for the octave and interoctave frequencies of 250 through 8,000 Hz. The intensity scale on the ordinate of the audiogram displays the hearing level (HL) of the signal in decibels (dB) ranging from a very faint level of -10 dB HL up to a very loud level of 110 to 120 dB HL.

#### **Speech Audiometry**

In addition to pure-tone thresholds, the basic audiologic evaluation includes measurement of the speech recognition threshold (SRT) and the assessment of word recognition performance.

**FIGURE 15-1.** Audiogram of a person with normal hearing in both ears.

The SRT serves primarily as a reliability check of the pure-tone threshold levels. Familiar two-syllable spondee words (e.g., hotdog, cowboy, baseball) are presented to each ear, and the patient is asked to repeat back these words until they can no longer understand or hear them. The intensity level at which 50% of the words are correctly repeated is defined as the SRT. The SRT should be within 10 dB of the pure-tone average (PTA) of 500, 1,000, and 2,000 Hz or the average of the best two of these frequencies. The SRT provides a means to cross-check the validity of the pure-tone thresholds. When there is a difference between the SRT and the PTA of 10 dB or greater, the source of this discrepancy should be determined. Causes include functional hearing loss, unusual audiometric configurations, language or cognitive disorders, patient misunderstanding of test instructions, and audiometer calibration or malfunction.

A hearing impairment may be reflected not only in a sensitivity loss but also in the reduced ability to understand speech, even when speech is sufficiently loud. Word recognition testing (speech discrimination) analyzes the patient's ability to understand speech using standardized lists of 25 to 50 single-syllable words. These lists are balanced to represent the phonetic content of everyday English speech. Word lists are presented to each ear separately and the patient is asked to repeat back the test words. The percentage of correct responses is the word recognition score. The test is initially presented at a comfortably loud level. Higher levels may be presented in an effort to determine the patient's best word recognition performance.

### Physiologic Hearing Assessment

#### Immittance Measurements

Physiologic assessment of the middle ear function is a routine part of the basic audiologic evaluation. Collectively referred to as immittance measurements, middle ear assessment includes tympanometry and acoustic reflex testing. Tympanometry provides information about the admittance, or compliance, of the middle ear transmission system and an estimate of middle ear pressure. This information is particularly useful in identifying

and differentiating among middle ear disorders. The acoustic reflex occurs when a sufficiently intense sound is presented to the ear causing contraction of the stapedius muscle and stiffening of the ossicular chain. Evaluating the integrity of the acoustic reflex provides information regarding not only the middle ear function but also other components of the reflex arc including the cochlea, seventh and eighth cranial nerves, and the lower brainstem.

#### Otoacoustic Emissions

A more recent addition to the audiologists' armamentarium, evoked otoacoustic emissions (OAEs) are low level sounds that emanate from the cochlea in response to sound stimulation. They are generated by healthy cochlear outer hair cells and impart insight into the functional integrity of the cochlea. In general, OAEs are observed in ears with normal to near-normal hearing sensitivity and can be greatly impacted by the presence of outer, middle, or inner ear disorders. OAEs are used in universal newborn hearing screening programs and in other cases in which patients are unable or unwilling to provide behavioral responses to sounds. They also provide confirmation of behavioral test results, serve as an objective method of monitoring ototoxicity, and assist in the identification of both functional hearing loss and neurologic disorders of the auditory system such as auditory neuropathy. While OAEs provide adjunctive information in hearing evaluation, they do not replace the audiogram.

#### Auditory-Evoked Potentials

When the ear is stimulated with sounds, a series of bioelectric events occur, that begin in the cochlea and quickly reach cortical structures. Much like electroencephalography (EEG), auditory-evoked potentials can be recorded from surface electrodes placed on the scalp and in or near the ear canal. The auditory responses are extracted from ongoing EEG activity by time-locked computerized averaging during repeated stimulation with transient or tonal stimuli. The evoked potentials most commonly used for audiologic assessment include electrocochleography (ECochG), the auditory brainstem response (ABR),

**FIGURE 15-2.** This audiogram shows that the patient has a mild conductive hearing loss. Note that the air conduction thresholds reveal a hearing impairment, but the bone conduction responses are within the normal range. Therefore, an air-bone gap is present.

auditory steady-state response (ASSR), and auditory middle latency response (AMLR). The primary clinical application of ECoG, which measures electrical potentials generated in the cochlea, is identification and monitoring of Meniere's disease. The ABR is used in newborn hearing screening programs to estimate peripheral hearing sensitivity in pediatric and uncooperative patients, in otoneurologic diagnosis, and for intraoperative monitoring during cerebellopontine angle surgery in which the auditory system is at risk for iatrogenic insult. The ASSR is used to estimate the degree, type, and configuration of peripheral hearing loss and appears to have a good predictive capacity in relation to the behavioral audiogram, especially in cases of severe and profound hearing loss. Less frequently used, the AMLR is thought to be generated in the auditory thalamocortical pathway. It can be used to predict auditory thresholds and may provide insight into neurologic diseases involving primary auditory pathways and auditory processing disorders.

### Audiometric Test Interpretation

#### Type of Hearing Loss

The general anatomic location of a hearing impairment can be determined by comparing the air conduction and bone conduction thresholds for each ear individually. A *conductive* hearing loss is present when air conduction results demonstrate a

hearing loss but bone conduction results are within the normal range (Fig. 15-2). The difference between air and bone conduction thresholds reflects the amount of conductive involvement and is called the *air-bone gap*. A conductive hearing loss may be caused by any disorder or dysfunction of the sound-conducting mechanisms from the external auditory canal through the middle ear. Although otoscopic examination may provide evidence of cerumen impaction, tympanic membrane perforation, or serous otitis media as the cause of a conductive hearing loss, there are also conductive pathologies that present with normal otoscopic examinations, such as otosclerosis or ossicular discontinuity. Tympanometry can provide useful information by describing the status of the middle ear system. Patients with conductive hearing loss typically have normal word recognition scores, because the sensorineural system is intact. Speech needs only to be presented at louder levels than normal to compensate for the conductive deficit.

When an equal amount of hearing loss is present by air conduction and bone conduction, the hearing loss is called a *sensorineural* loss (Fig. 15-3). The hearing disorder could be located in the cochlea, the associated neural pathways, or both. The specific etiology of the sensorineural hearing loss cannot be determined by the audiometric results alone. Word recognition test results often provide important diagnostic

**FIGURE 15-3.** This audiogram shows that the patient has a sensorineural hearing loss: both the air conduction and the bone conduction thresholds are similarly depressed.

**FIGURE 15-4.** This audiogram shows that the patient has a mixed hearing loss. Although both the air conduction and the bone conduction thresholds are reduced, a greater impairment is evident for air conduction.

insight into the site of lesion of sensorineural hearing loss. In general, cochlear involvement demonstrates speech discrimination scores that are reduced to a degree compatible with the degree of hearing loss. The greater the degree of sensory (cochlear) hearing loss, the poorer the word recognition. On the other hand, neural auditory disorders often yield speech discrimination scores disproportionately poorer than would be expected from the pure-tone thresholds. That is, a 40-dB HL sensorineural hearing loss with a 72% word recognition score would be consistent with cochlear involvement, whereas a similar amount of hearing loss with only a 10% word recognition score would suggest the possibility of eighth cranial nerve involvement. From a rehabilitative standpoint, the better the speech discrimination score, the better the prognosis for hearing aid success, as there is less distortion in the auditory system. Tympanometry is most often normal in cases with sensorineural hearing loss, while acoustic reflex patterns may help to differentiate sensory from neural causes.

A loss of hearing sensitivity for bone conduction with a greater loss for air conduction represents a *mixed* hearing loss (Fig. 15-4). A sensorineural hearing loss is present, as reflected by reduced bone conduction thresholds, and conductive loss also is present, as reflected by the air-bone gaps. Tympanograms may provide insight into middle ear problems contributing to the conductive component of a mixed hearing loss.

In addition to hearing loss resulting from damage or dysfunction of the peripheral hearing mechanisms, damage or dysfunction of the central auditory pathways can impact hearing abilities. Central auditory processing disorders most often are manifested as difficulty understanding speech in noise or situations in which the signal is degraded, such as a reverberant room. Auditory test results will frequently show normal hearing sensitivity and normal speech recognition ability in quiet. Performance declines are observed on degraded or difficult speech recognition tests including speech in noise and filtered speech, measures of frequency and temporal processing, dichotic listening, and/or on electrophysiologic measures of the central auditory pathways such as the ABR and AMLR. Common causes include head trauma, stroke, neurodevelopment disorders, genetic factors, tumors,

neurologic disease, aging, and long-term sound deprivation (130). While less amenable to traditional hearing aid amplification, persons with auditory processing disorders may benefit from other types of assistive listening systems, as well as therapeutic auditory regimens.

### Degree and Configuration of Hearing Loss

The results obtained from the air conduction evaluation provide quantitative information as to the magnitude of hearing loss. Classification systems have been devised in an effort to relate the amount of air conduction hearing loss to the expected degree of handicap imposed by a hearing loss. Such systems typically use the PTA to estimate various hearing loss categories and the expected impact on speech understanding. The most commonly used PTA is a three-frequency average of 500, 1,000, and 2,000 Hz, although a four-frequency PTA that also includes 4,000 Hz may be more reflective of functional hearing. Table 15-5 gives an example of such a classification system (131). In addition to type and degree of hearing loss, the configuration or shape of the pure-tone audiogram is helpful in describing and understanding the impact of a hearing loss. Classification schemes include flat, sloping, and rising configurations. A sloping audiogram has a greater amount of hearing loss in the high frequencies, whereas a rising configuration refers to a greater amount of hearing loss in the low frequencies.

**TABLE 15.5** Classification System for Degree of Hearing Loss

Pure Tone Average	Classification
0–15 dB HL	Normal
16–25 dB HL	Slight
26–40 dB HL	Mild
41–55 dB HL	Moderate
56–70 dB HL	Moderately severe
71–90 dB HL	Severe
91 dB HL and above	Profound

Any type of audiometric classification system must be interpreted with caution because most are based on pure-tone air conduction thresholds alone and do not incorporate the effects of speech discrimination difficulties, etiologic factors, the type of hearing loss, or hearing loss configuration. In addition, those with similar amounts of pure-tone hearing loss may be affected in very different ways, depending on lifestyles, hearing demands, and other psychosocial factors.

### Causes of Hearing Loss

Hearing loss can be caused by or occur in conjunction with a variety of diseases and disorders, genetics, aging, trauma, or ototoxicity. The following description provides an overview of the major causes of hearing loss including conditions affecting the outer, middle, and inner ear as well as the central auditory pathways.

### Hereditary Hearing Loss

Hereditary hearing loss accounts for approximately 50% of hearing loss identified in newborns. Approximately 70% of genetic hearing loss is nonsyndromic, and approximately 30% is syndromic. Nonsyndromic hearing loss is most often sensorineural. It is typically classified by its mode of transmission, which is recessive in approximately 70%, dominant in approximately 30%, x-linked in approximately 1% and mitochondrial in approximately 1%. Nonsyndromic recessive hearing loss is most often congenital and profound, whereas nonsyndromic dominant hearing loss is more variable in presentation with congenital or delayed onset. There are at least 400 syndromes with hearing loss as a phenotypic feature. Syndromic hearing loss is quite variable in its presentation. It can be conductive, mixed, and sensorineural; it can range from slight to profound; it can be stable or progressive; and it can involve one or both ears (132). The Hereditary Hearing Loss Homepage (133) provides a comprehensive review of the genetics of hereditary hearing loss, which is beyond the scope of this chapter.

### Outer Ear

When hearing loss originates in the external auditory canal, it usually is related to a mechanical obstruction in the form of cerumen (ear wax) or a foreign body. Accumulation and impaction of excess cerumen in the external ear canal is one of the most common reasons that patients seek care for hearing- and ear-related symptoms. Elderly, pediatric, and cognitively impaired individuals are at higher risk for cerumen impaction. This is especially common in elderly residents of nursing homes where the prevalence of cerumen impaction may be as high as 65% (134). The resultant conductive hearing loss ranges from slight to mild and is most often resolved after removal of the impacted cerumen from the ear canal. In addition to hearing loss, excessive ear wax may prevent benefit from or cause damage to hearing aids.

Infections of the ear canal (otitis externa) can occur in acute, chronic, and malignant forms. They are most commonly caused by bacterial infection and more rarely may have

a viral or fungal origin. Signs and symptoms include ear pain, drainage, edema, inflammation, itching, and aural fullness. If the infectious process causes the ear canal to become swollen shut, there is a resultant conductive hearing loss. Medical management includes treatment of pain and control of infection. Hearing aid use may need to be discontinued during periods of active infection (135).

### Middle Ear

Otitis media is an infection, or inflammation, of the middle ear usually with fluid (effusion) behind an intact tympanic membrane. Acute otitis media (AOM) occurs frequently in children and is the most common infection for which antibacterial agents are prescribed in the United States. When treated successfully with medications or middle ear surgery, AOM is alleviated or controlled, but when left untreated, complications of the disease may spread to involve intracranial or intratemporal structures. Otitis media with effusion (OME) indicates a situation where the middle ear is filled with fluid but typically without signs or symptoms of acute ear infection other than hearing loss. The audiometric presentation of a person with otitis media ranges from a slight to moderate conductive hearing loss, typically with a rising configuration. The tympanogram is flat indicating absence of middle ear system mobility, and the stapedial reflex is absent.

In addition to hearing loss, complications of otitis media include cholesteatoma, an inclusion of keratinizing squamous epithelium that proliferates within the temporal bone. A cholesteatoma can block sound transmission or cause erosion of the middle ear ossicles, resulting in a conductive hearing loss. When a cholesteatoma erodes the temporal bone, it puts the patient at risk for mixed or sensorineural hearing loss, vertigo, and/or meningitis. Mastoid surgery is the means by which cholesteatoma is eradicated. The primary surgical goal is to rid the ear of the cholesteatoma itself. Secondarily, reconstruction of the tympanic membrane and/or ossicles may be necessary to preserve or improve hearing. In many cases, hearing aids will be required following the eradication of the cholesteatoma (137).

Glomus tumors are the most common neoplasm of the middle ear and the second most common tumor of the temporal bone in adults (138). The most frequent initial symptoms are pulsatile tinnitus and hearing loss. On otoscopic examination, a glomus tympanicum appears as a red-blue mass behind or involving the tympanic membrane. Conductive hearing loss is the most common audiometric finding occurring in up to 52% of people with these tumors as the result of reduced ossicular mobility or destruction. As the tumor grows medially, there is cochlear involvement resulting in a mixed or sensorineural hearing loss. Surgical excision is the treatment of choice unless contraindicated by the patient's medical condition or tumor location and biology (138).

Otosclerosis is a progressive, focal disease of the ear in which there is excessive resorption of bone, which is replaced by soft new bone that gradually changes into a dense sclerotic mass. In its early stages, otosclerosis hinders transmission of sound by the ossicular chain due to fixation of the stapes footplate in the oval

window. At this stage, the hearing loss is typically conductive and mild, and the patient is a good candidate for a stapedectomy, a corrective surgery in which the stapes is partially removed and replaced by a prosthesis. In its later stages, otosclerosis can invade the inner ear causing a mixed but primarily sensorineural hearing loss that can be of severe to profound degree. Hearing aid amplification is often beneficial for those who elect not to have surgery or who are not candidates for surgery.

### **Inner Ear**

#### ***Presbycusis***

Presbycusis is the term used to describe age-related hearing loss. The most common audiologic presentation of age-related hearing loss is a sloping, high-frequency sensorineural hearing loss. Hearing thresholds decline gradually with age, beginning as early as the third decade in men and the fifth decade in women. Concomitant to the loss of sensitivity is a reduction in the ability to understand speech, especially in background noise and reverberant rooms or when the speaker talks at a rapid rate or with accented speech. Reduced cognitive abilities can further compound these problems. Age-related changes in the ear include deterioration of structures within the inner ear, including the stria vascularis, cochlear hair cells, and dendritic fibers of the eighth nerve. In most cases, age-related changes occur within the milieu of other potential causes of hearing loss, including genetic susceptibility, noise exposure, ototoxic drugs, and ear disease. Most persons with presbycusis are able to obtain benefit from hearing aids used alone or in conjunction with other amplification devices.

#### ***Noise-Induced Hearing Loss***

Exposure to high levels of sound can cause damage to the hair cells in the cochlea resulting in noise-induced hearing loss (NIHL). Approximately 26 million Americans aged 20 to 69 have hearing loss attributable to noise exposure (130). More recently, NIHL in pediatric populations has become a concern. Harmful sounds include both impulse and continuous noises. Hearing loss can occur suddenly after a single noise exposure but more commonly occurs gradually as the result of the accumulative effect of years of noise exposure. The hearing loss begins in the high frequencies with a characteristic notch around 4,000 Hz. Over time with repeated exposure, NIHL spreads to the mid and low frequencies with deleterious effects on the ability to hear and understand speech, resulting in the need for amplification. Categories of activities associated with noise exposure include military (e.g., weapons, explosives), occupational (e.g., loud machinery, heavy equipment), and recreational (e.g., hunting, loud music, power tools). While personal hearing protection devices such as ear plugs and ear muffs provide some reduction in sound levels, use of these among individuals exposed to harmful noise levels is not always consistent.

#### ***Ototoxic Drugs***

There are a number of drugs that may be toxic to the inner ear and may cause hearing loss, tinnitus, balance dysfunction, or a

combination of these symptoms. The most common ototoxic drugs include aminoglycoside antibiotics, cisplatin, high-dose salicylates, and loop diuretics. The typical ototoxic hearing loss is bilateral and sensorineural. It begins in the high frequencies and, with continued administration of the ototoxic agent, spreads to include lower frequencies while high-frequency hearing continues to decline. Eventually, the patient may experience significant communication difficulties necessitating use of amplification. In general, aminoglycosides cause a gradual onset of hearing loss, while cisplatin can cause a significant hearing loss after a single treatment. Aminoglycosides and cisplatin cause permanent hearing loss, while the hearing loss resulting from high-dose salicylates and loop diuretics is often reversible.

#### ***Infection and Immunologic Disorders***

Labyrinthitis, an infection of the inner ear, is most commonly caused by direct extension from the middle ear; that is, as a complication of AOM or chronic suppurative otitis media with cholesteatoma. Congenitally acquired illnesses and complications of meningitis may also cause labyrinthitis. Inner ear infections are quite worrisome, as they often cause significant and even permanent sensorineural hearing loss or vertigo and can lead to meningitis, brain abscess, or death. Treatment includes antibiotics, steroids, and, in some cases, myringotomy and placement of middle ear ventilation tubes (127). Depending on the degree of resultant hearing loss, the patient may benefit from hearing aids, or in some cases, a cochlear implant may be necessary. Systemic infections such as acquired syphilis and Lyme's disease can also cause sensorineural hearing loss. Treatment consists of antibiotics with corticosteroids to manage the sensorineural hearing loss. Depending on the degree of hearing loss, hearing aids may be indicated.

Generalized inflammatory conditions and autoimmune illnesses occurring in the absence of infection may also affect the auditory system. They may affect the ear singularly as in autoimmune inner ear disease (AIED) or have typical systemic symptoms as exemplified by sarcoidosis, Wegener's granulomatosis, polychondritis, or systemic lupus erythematosus.

#### ***Trauma***

Injury to the ear can occur as the result of head trauma in which damage may be limited to a single part of the ear, or it can be more pervasive involving the outer, middle, and inner ear as well as central structures. Longitudinal fractures of the temporal bone most often cause conductive or mixed hearing loss, while transverse fractures of the temporal bone most often result in a profound sensorineural hearing loss and vertigo. Self-cleaning or probing the ear canal with a foreign body, such as a cotton swab, is a frequent cause of ear canal lacerations, tympanic membrane ruptures, dislocation of the middle ear ossicles, and inner ear injuries. The external ear is also susceptible to injuries such as frostbite, lacerations, and burns.

#### ***Neoplasms***

The most common tumor of the temporal bone is the acoustic neuroma (vestibular schwannoma) that accounts for 80% of

intracranial tumors in the cerebellopontine angle. Vestibular schwannomas make up almost 10% of all intracranial tumors and most commonly arise from the vestibular portion of the eighth cranial nerve (127). Patients typically develop unilateral sensorineural hearing loss with poor speech discrimination, tinnitus, and sometimes vertigo. Treatment options include surgical resection to remove the tumor or highly focused radiation therapy. Although hearing preservation is possible in some patients, the primary goal is the removal of the neoplasm. Post-treatment benefit from a hearing aid may be possible in some cases.

### Medical-Surgical Rehabilitation

Medical or surgical treatment of hearing loss is most often available for people with impairments involving the conductive mechanisms of the auditory system. Hearing impairment originating in the middle ear system may be treated with otologic surgery. Surgical procedures such as myringoplasty (i.e., repair of tympanic membrane perforation), tympanoplasty (i.e., ossicular reconstruction), stapedectomy for otosclerosis, and myringotomy with placement of ventilating tubes for middle ear effusion often can correct the conductive hearing loss.

Otologic surgery sometimes is required for treatment of life-threatening disease and not for hearing improvement. Pathologic conditions such as cholesteatoma, glomus tumor, or chronic middle ear disease often necessitate surgery. In addition, otoneurosurgery is necessary for sensorineural impairment caused by acoustic neuromas. Otologic treatment of congenital or hereditary sensorineural hearing loss, NIHL, presbycusis, and most other types of sensorineural impairments is not possible at this time. Perhaps the greatest advance in the surgical rehabilitation of sensorineural impairments is now available with the development of the cochlear implant for severe to profound hearing loss.

### Hearing Aid Amplification

Although hearing loss due to conductive disorders may often be successfully alleviated with medical or surgical intervention, the most common site of lesion that causes hearing loss is the cochlea. Of all patients with cochlear hearing loss, fewer than 5% can be helped medically. Hearing aids are the principal resource for improving communication and reducing hearing handicaps in persons with sensorineural hearing loss. Significant improvements in hearing aid technology have resulted in greater flexibility in selecting and fitting hearing aids for most hearing losses. The past decade has witnessed innovations resulting in a wide assortment of hearing aids, varying both in physical size and in technological sophistication. Yet, despite the substantial benefits provided by hearing aids, only 23.5% of people with hearing loss own hearing instruments (132).

### Hearing Aid Candidacy

It is a disservice to the patient to discourage a hearing aid trial because of the misconception that a hearing aid does not

help “nerve deafness.” While some physicians may tell their patients that they can probably “get by” without a hearing aid and should wait until the hearing loss progresses, consultation with an audiologist will provide the patient with an individualized opportunity to make amplification decisions that best suit their lifestyle and listening needs. Discouraging a hearing aid trial for an individual with communicative difficulties and a potentially remediable hearing loss serves only to invite isolation and frustration. Unless assurance and support are provided, hearing-impaired patients may unfortunately postpone and avoid the use of amplification. Referral to an audiologist for hearing assessment and hearing aid evaluation provides patients an opportunity to understand their hearing loss and its impact on daily function, as well as candidacy for the many types of amplification systems suitable for their individual needs.

### Hearing Aid Selection and Fitting

Current hearing aid styles include devices that fit behind-the-ear, in-the-ear, in-the-canal, and completely-in-the-canal. Because many people unfortunately associate hearing loss with the stigma of aging, the introduction of smaller devices, which fit entirely in the ear canal, has had obvious cosmetic appeal. Newer and smaller behind-the-ear hearing aids that feature a slim tube and an open-fitting have resulted in a recent swing of the pendulum back to behind-the-ear hearing aids. This type of fitting helps to eliminate the sensation of an occluded ear and has proven to be advantageous for those with mild to moderate hearing loss as well as hearing loss confined to the high frequencies. Selection of appropriate hearing aids must take into account degree and type of hearing loss, loudness tolerance, communication needs, manual dexterity, vision impairments, and personal preference.

Hearing aids no longer merely provide analog, linear amplification. The vast majority of current hearing aids are digital, and include many features that enhance the amplified signal and tailor the sound to the specific needs of the individual hearing aid user. Compression circuitry reduces the amplification of loud sounds to comfortable levels without removing valuable informational content. In addition, automatic loudness-adjusting circuits automatically decrease amplification of continuous background sounds in an effort to improve speech understanding in noise. Hearing aids without volume controls automatically increase the loudness of soft sounds while decreasing loud level inputs. Frequency compression, a more recent hearing aid feature, modifies the bandwidth of the amplified signal so that it is within the patient’s frequency range of audibility. There are also hearing aids that offer several programs for use at the listener’s discretion, because a single amplification paradigm may not be optimal for all listening situations. One may choose a wide frequency amplification for quiet environments, another program that eliminates low frequencies for noisier situations, or a program specifically suited for telephone use or listening to music. Most hearing aids are digitally programmed by a computer through the use of a microchip within the hearing aid itself. Individual programming of

the hearing aid enables the audiologist to make significant modifications to meet the patient's needs. Multiprogram hearing aids may include a user-operated remote control to facilitate program changes or volume changes. Fixed or adaptive directional microphones help to improve speech understanding by improving the signal-to-noise ratio. Bluetooth technology enabling wireless communication between the hearing-aid and other electronic devices such as cell phones and MP3 players helps to keep the technology-savvy hearing aid user connected.

After the initial history, examination, and evaluation, the audiologist will determine the need for and recommend the type of hearing aids, specify the acoustical and technological requirements of the hearing aids, program and fit the hearing aids, and provide training in the use of amplification. The potential advantages and limitations of hearing aids are reviewed with the patient, and follow-up is provided during the adjustment period after the hearing-aid fitting. Most states mandate a right-to-return period, which provides patients with the opportunity to wear the hearing aids in their own everyday listening environments to evaluate benefit, comfort, and overall satisfaction with the instruments. If they are unsatisfied for any reason, they can return the hearing aids at little or no cost during this period of time. The audiologist assists the patient during this transition and may make further adjustments or changes to the devices to ensure that the hearing-aid fitting is optimal. In addition to fitting and programming the hearing aids, the audiologist provides counseling in effective communication and auditory training to enhance and maximize listening skills.

### Assistive Listening Devices

Although substantial improvements have been achieved in hearing-aid technology, factors such as distance from a speaker, background noise, reverberation, and declines in central auditory processing have deleterious effects on speech intelligibility that cannot be overcome through the use of hearing aids alone. Assistive listening devices (ALDs) comprise a number of situation-specific amplification systems designed for use in difficult listening environments. ALDs commonly use a microphone placed close to the desired sound source (e.g., a television, theater stage, or speaker's lectern from which sound is directly transmitted to the listener). Transmission methods include infrared light, FM radio waves, and induction loops. Such transmission of sound directly to the listener improves the signal-to-noise ratio. That is, the desired sounds are enhanced while competing extraneous noises are decreased, thus improving understanding. Public Law 101-336, the Americans with Disabilities Act (1990), requires assistive listening technology in places of public accommodation. ALDs in many churches, theaters, and classrooms enable hard-of-hearing persons to avoid the isolation imposed by the inability to hear a sermon, play, or public address.

Amplified telephones, low-frequency doorbells, amplified ringers, and closed-captioned TV decoders are just a few examples of the number of devices currently available for the hearing impaired for everyday use. Alarms are available with low-frequency signals for those persons with high-frequency hearing losses who cannot hear the higher pitch alarms. Flashing alarm

clocks, alarm bed vibrators, and flashing smoke detectors are other alerting options for severely hearing-impaired individuals.

### Cochlear Implants

The cochlear implant is a surgically implanted auditory prosthesis designed to provide acoustic stimulation for persons with bilateral severe to profound sensorineural hearing loss who derive little or no benefit from hearing aids. The device bypasses the cochlear hair cells and provides direct electrical stimulation of the residual eighth nerve fibers in the cochlea. The FDA approved cochlear implants for adults in 1984 and for children as young as 2 years in 1990. In 2000, the age of eligibility was lowered to 12 months. As of 2009, more than 41,500 adults and 25,500 children in the United States have received cochlear implants (127). Candidacy for a cochlear implant is evaluated by a team, including an otolaryngologist and audiologist. Prospective implant candidates require an extensive audiologic evaluation to document that hearing aids are not beneficial and an otologic evaluation to determine implant and surgical candidacy. The implant operation involves placing an electrode array into the cochlea and connecting it to an internal coil, which is placed under the skin behind the pinna and is aligned with an external coil placed behind the ear. After the healing period, the patient is fitted with an external microphone, speech processor, and transmitter. The microphone, usually worn at ear level, feeds electrical impulses to the speech processor that resembles a body-type or behind-the-ear hearing aid. The processor digitally encodes the sound and sends these electrical signals to the external coil, which transmits the signal to the internal coil and then to the electrodes in the cochlea. Current flows between the active electrodes, stimulating remaining eighth nerve fibers and producing a sensation of sound. The audiologist programs the speech processor to identify and establish a sound map that works best for the individual patient. Rehabilitation includes repeated visits to program and fine-tune the sound map and intensive auditory training. Patient commitment to the full rehabilitative process is vital to success with the implant.

While a cochlear implant does not provide normal hearing, users may derive many benefits including recognition of environmental sounds and ability to understand spoken language with, and in some cases without, speech reading cues. Benefits for children implanted early in life may include enhanced development of speech and language skills as well as improvement in overall literacy. Current evidence suggests that binaural implantation and bimodal fittings (combining a cochlear implant and hearing aid in opposite ears) may become the standard of care for pediatric cases.

### Speech Reading and Auditory Training

Hearing aids and other amplification systems provide the hearing-impaired individual with access to auditory information, but this alone does not guarantee comprehension. Supplementary information obtained through speech reading (lip reading) and auditory training to improve listening skills is an important components of successful hearing rehabilitation.

Speech reading is the use of visual cues in the recognition of speech and incorporates the interpretation of facial expressions, body movements, and gestures. Everyone uses speech reading to some extent, although usually we are not conscious of the importance of visual input in helping us to recognize what is being said. Many people with hearing impairment, particularly those with gradually progressive hearing loss, develop this skill through necessity. Although a considerable amount of the speech signal can be perceived visually, only about one third of English speech sounds are clearly visible. Certain sounds (e.g., *f* and *th*) are relatively easy to see on the lips, whereas others, such as *k* and *g*, are not visible, and some (e.g., *p* and *b*) are indistinguishable from one another.

Auditory training teaches the hearing-impaired individual to make the most effective use of the limited auditory cues imposed by the hearing loss as well as the additional auditory information delivered by the hearing aid. While the benefits of auditory training programs have been documented, such programs have not been time- or cost-effective. Recently, computer-based, adaptive, auditory training programs have become available (e.g., Listening and Communication Enhancement) that provide a home-based, individualized approach to aural rehabilitation.

Aural rehabilitation strategies also teach the hearing-impaired person to become a more assertive listener. Those who quietly accept hearing loss or not understanding speech merely invite continued social isolation. The hearing-impaired listener needs to inform others of his or her impairment and advise them as to the most effective means of communication. Self-help groups are available, most notably the Hearing Loss Association of America, which offers local groups, as well as an active national organization and journals.

Although management of hearing loss with hearing aid amplification, ALDs, cochlear implants, and aural rehabilitation therapy does not cure the impairment or restore hearing and communicative efficiency to normal, such approaches represent the best treatments available at this time. They will improve the ability of most people to communicate effectively and reduce the handicapping consequences of hearing loss.

## ACKNOWLEDGMENTS

# Sexuality and Disability

## INTRODUCTION

Sexuality is an integral part of being human and is a vehicle to demonstrate attraction, intimacy, and commitment. Because of this, sexuality persists beyond reproductive years and/or good health. Persons with disabilities often feel that since significant changes to their sexuality are not life threatening, sexual concerns do not merit attention by health care professionals. Nothing can be further from the truth. Sexuality is highly important and medically legitimate and greatly affects quality of life. When surveyed about what “gain of function” was most important to their quality of life, men and women with spinal cord injury (SCI) stated that sexuality was a major priority even above the return of sensation, ability to walk, and normal bladder and bowel function (1), that SCI altered their sexual sense of self, and that improving their sexual function would improve their quality of life (2,3).

In this chapter, we focus on sexuality in those persons with physical disability versus mental, cognitive, or developmental disabilities. When a condition becomes chronic or gradually debilitating, expectations of *recovery* must give way to pursuit of *adaptation* (4). “Sexual rehabilitation” not only implies salvaging and restoring remaining function but also implies remaking and readjusting. Only in the arena of sexuality can rehabilitation go beyond the local affected area. Loss of physical, sensory and motor options forces an appreciation of the power of “brain or cerebral sex” and the development of evolved sexual experience through the process of “neuroplasticity.” This is best explained by the analogy of how, despite the “hardware” being altered by disability, the “software” can still be intact and adaptable (5). Research is just starting to address the potential of “sensory substitution” in persons with disability (6). In the medical treatment of sexuality after disability, the mind-body interaction cannot be forgotten by the clinician or the therapeutic value of this potential is lost.

## THE COMPLEXITY OF SEXUAL FUNCTIONING

### Models of Sexual Function

In 1966, Masters and Johnson (M&J) proposed a physiological model of sexual response after studying over 600 able-bodied men and women in a laboratory setting where details of genital, breast, skin, muscle, and cardiovascular functions were observed (7). Since the M&J model, many more models have

been proposed embracing the biopsychosocial approach to sexuality, especially for women (8). A recent, clinically applicable model of human sexual response useful for both sexes (4) is well suited to the complexity of the disability population, who may not be neurologically intact. However, the M&J model is still helpful in understanding the neurophysiology of sex and in defining the sexual dysfunctions.

The M&J model describes a four-phase “sexual mountain” of rising and declining sexual arousal: (a) excitement, (b) plateau (high arousal before orgasm), (c) orgasm, and (d) resolution (the reversal and/or dissipation of phase 1). Pelvic vasocongestion and neuromuscular tension results in tumescence and/or erection of the erectile tissues in both men and women and, additionally in women, vaginal lubrication and accommodation (lengthening and uterine lifting). Cardiovascular and respiration parameters increase, and sweating appears. During the “preorgasmic” phase, men have maximal erection and rigidity and approach ejaculatory inevitability, and in women, the outer third of the vagina forms a thickening called the “orgasmic platform.” Orgasm is a pleasant experience recognized in the genital area, brain, or total body and is accompanied by involuntary rhythmic contractions of the pelvic floor muscles in both men and women as well as smooth muscle contractions of internal accessory sexual organ and structures. The orgasmic phase has the maximal heart rate (HR), blood pressure (BP), and respiratory rate in neurologically intact persons. Ejaculation, the process of forward (antegrade) seminal fluid expulsion through the urethra, is usually concomitant with orgasm in men but can be separated in neurological conditions. The final resolution phase is characterized by gradual reversal of the tumescence, pelvic vasocongestion, neuromuscular tension, and cardiovascular parameters noted above. Men, but not women, have a physiological refractory period (7), and women have the capacity to have extended, repeated (multiple), or compounded orgasms. However, some men also report the capacity for multiple orgasm (9).

### Definitions of Sexual Dysfunctions

Male and female sexual dysfunctions are multifactorial, involving physiological, psychological, social, and emotional components. Sexual desire or libido is especially complex and under central neurophysiologic control. Kaplan (10) defines it as “the experience of specific sensations that motivate the individual to initiate or become responsive to sexual stimulation.” If a person with disability experiences a change in drive, it is most

often a reduction, known as *hypoactive sexual desire disorder*. In rarer cases, sexual drive may be increased due to brain stimulation from injury (i.e., hypersexuality of the Kluver-Bucy syndrome) or medications (replacement of the sex excitatory neurotransmitter dopamine [DA] in a patient with Parkinson's disease). Three other disorders of sexual dysfunction are clinically identified using the M&J model: arousal disorders (disorders of male penile erection [or erectile dysfunction, ED] and female subjective and objective arousal disorders), *ejaculatory dysfunction*, and *orgasmic disorders*. Problems within these phases in both sexes can include fertility issues and pain specific to sexual activities (*dyspareunia*). A full definition of sexual dysfunctions can be found elsewhere (11).

## SEXUAL NEUROPHYSIOLOGY

Both somatic and autonomic nerves provide important sexual afferent and efferent communication between the brain and periphery. Autonomic nerves are activated by stretch or lack of oxygen, rather than by touch or temperature (12). In the somatic system, tactile inputs include light touch, temperature, pressure, vibration, and pain. It appears that both somatic and autonomic nerves appear critical to recognize stimuli as "sexual" (12). The cerebral evaluation of skin and visceral stimulation; of visual, gustatory, and auditory inputs; and of fantasy and emotion forms either a sexually excitatory or inhibitory signal. This generated neuronal "trigger," coordinated in the limbic system, hypothalamus, and other midbrain structures, is carried distally through the brainstem and spinal tracts and can be modulated by mood, hormones, emotions, and physical factors (4). In everyday life, this signal is usually inhibitory, until engagement of sexual activity is deemed appropriate and excitatory signals dominate, instigating the triggering of spinal cord reflexes for sexual function. Performance anxiety, distraction, and fear of negative consequences of being sexual (i.e., ED) can cause the supratentorial inhibition on the spinal cord reflexes to remain. In chronic disease or neurological conditions, signals may be directly disrupted by nerve injury or nerve degeneration, the physiology of an end organ and its ability to respond to the stimulus can be altered, or pain or other limitations can cause distraction away from the sexual focus, rendering sexual response unreliable.

Once the descending signal has passed down the spinal cord, the pelvic sexual organs receive their information from the spinal cord via three nerve pathways: (a) sacral parasympathetic (pelvic nerves and pelvic plexus), (b) thoracolumbar sympathetic (hypogastric nerves and lumbar sympathetic chain), and (c) somatic (bilateral pudendal nerves) (13). More attention is being paid to try and preserve these nerve tracts in pelvic surgery to reduce the amount of resulting sexual dysfunction (14,15). Sexual arousal leads to genital erectile tissue engorgement and pelvic vasocongestion via vasodilatation of arteries and smooth muscle relaxation. In women, lubrication depends on both intact innervation and normal estrogen levels (16), and in men, internal accessory organ function (including

the production of semen) and erection are dependent on adequate testosterone levels.

There are two neurological pathways for *genital arousal*: reflexogenic and psychogenic. While psychogenic and reflexogenic pathways can act independently, they usually act synergistically to determine the genital response via a final common pathway involving a sacral parasympathetic route (13). The *reflexogenic pathway*, triggered by direct stimulation of the genital organs, has an afferent component conveyed by the pudendal nerve to the S2–4 segments of the spinal cord (17). The responding efferent component returns through the sacral parasympathetic center, contributing fibers to the pelvic nerve and onto the cavernosal nerves at the genitalia. The *psychogenic pathway* is of supraspinal origin (auditory, imaginative, visual, etc.) involving the medial preoptic nucleus (MPOA), paraventricular nucleus of the hypothalamus, and reticular activating systems (the latter involved with nocturnal arousal during REM sleep) (14). The long efferent tracts from the central nervous system between cortex, cord, and autonomic nervous system must be intact to elicit the thoracolumbar sympathetic center and the sacral parasympathetic center (17). Complete spinal cord injury (SCI) above the level of the psychogenic pathway eliminates the connection to it and the natural supratentorial inhibitory control, enhancing the reflexogenic mechanism initiated by touch (14). SCI involving the lumbosacral region results in loss of reflexogenic but not psychogenic capacity, since the pathway from the brain to the thoracolumbar center is still intact. The sympathetic nervous system can maintain genital arousal capacity after injury to parasympathetic pathways (13), and has a role in the development of psychogenic arousal (18). Both men and women undergo measurable genital arousal during rapid eye movement (REM) sleep (16,19). In men, the presence of REM sleep (morning) erections is a sign that daytime erection problems are *more likely* psychogenic in nature. An exception is in multiple sclerosis (MS), where, despite organic disturbance with daytime, erotic erections, nocturnal erections can be frustratingly preserved (20).

At the genital level, cavernosal smooth muscle relaxation results in vasocongestion, tumescence, and elongation of the erectile tissue in both men and women. The tunica albuginea, a fibroelastic stocking surrounding the corpora cavernosa, becomes stretched with tumescence, tightening its elastic fibers and kinking the emissary veins that pierce it. This occludes the venous blood outflow while high pressure arterial inflow continues. In men, this veno-occlusive mechanism, along with bulbocavernosus (BC) muscle contraction, results in a rigid erection and ischiocavernosus (IC) muscle contraction helps propel ejaculated semen (14,21). In women, the veno-occlusive mechanism is less prominent due to a less effectual tunica (16). Vaginal lubrication (a plasma transudate from the blood circulating through the vessels of the vaginal epithelium), lengthening of the vagina, and uterine, urethral, labial, and pelvic ligament vasocongestion occurs with female arousal (15). Passive dilation of the vagina results in a reflex contraction of both the BC and IC, indirectly affecting the clitoris and sensory perception of the clitoris (22). Spasm of either the BC or IC muscles, or injury to their pudendal innervation can

effect subjective sexual arousal and orgasm. Priapism can occur in both sexes, and a persistent arousal syndrome, potentially of organic origin, has been newly recognized in women (23,24).

While arousal is predominately parasympathetic, *ejaculation* is primarily a sympathetic phenomenon. Preganglionic sympathetic fibers leave the spinal cord from the first and second lumbar segments, synapsing and eventually distributing to the vas deferens, seminal vesicles, and the prostate through the hypogastric nerves, stimulating smooth muscle contractions (12). Ejaculation occurs in two phases: seminal emission (sympathetic T10–L2) and propulsatile ejaculation or expulsion (parasympathetic S2–4 and somatic). Seminal emission involves transport of semen into the prostatic urethra via the ejaculatory ducts in the prostate. The sympathetic hypogastric nerve (L1, L2) activity closes the bladder neck to prevent retrograde ejaculation. A sense of impending “ejaculatory inevitability” proceeds propulsatile ejaculation and the seminal bolus is then propelled distally out the urethral meatus (14). Orgasm usually occurs with ejaculation, but they are not synonymous and are separate neurological entities.

*Orgasm* appears to be relayed through both the somatic and autonomic systems (23), but neurologically, orgasm is the least understood of the sexual phases. It is a complicated combination of local spinal cord reflexes and cerebral and autonomic influences, any of which could potentially dominate in any one orgasmic experience or be adequate within themselves. “Orgasm” after disability may include orgasmic attainment without genital stimulation (i.e. “eargasms” after SCI, orgasm arising from breast stimulation alone, etc). For example, about half of men and women with complete SCI can still experience orgasm, and a few neurophysiological theories have been proposed for this phenomenon (25). Strength of the pelvic floor contractions (somatic), the degree of engorgement of the internal genitalia (autonomic), subjective awareness of internal genitalia contractions (i.e., uterine), duration and degree of brain arousal, and interpretations of cardiovascular alterations with sexual activity are all factors in the subjective intensity of orgasmic release. While estrogen does not seem to influence the orgasmic potential in women, low androgen levels make orgasm more difficult to reach in both men and women (26). Oxytocin levels may rise during arousal and orgasm, and prolactin levels remain elevated after orgasm (23), but the significance of this is not known.

## DISABILITY-RELATED DISRUPTIONS TO SEXUAL FUNCTION

Disability can affect sexual function through four basic mechanisms (4):

1. *Direct* effects of vascular, neurological (including pain), hormonal, anatomical, or other damage to any area functionally connected to the sex response
2. *Indirect* effects of the medical/psychological condition, such as changes to perception or judgment, sensory or motor

alterations, bladder and bowel incontinence, spasticity, tremor, fatigue, anxiety, chronic pain, etc.

3. *Iatrogenic* effects of treatment (e.g., radiation, surgery, medication, and chemotherapy)
4. *Contextual factors*, that is, the biopsychosocial complexity and the situational components.

Contextual factors are especially critical in long-term care, where issues such as freedom of sexual expression, choice making capacity, right to privacy, and caretaker issues and responsibilities must be addressed (27).

## Medications

It is well known that many drugs interfere with sexual functioning. The *central* neurotransmitters involved in the descending signal through the thalamospinal tracts are the excitatory neurotransmitters DA and noradrenaline (NA), whereas serotonin is generally inhibitory (4). Drugs that reduce NA, such as sympatholytic antihypertensives, negatively affect sexual function. DA blockers (e.g., antipsychotics) will impair libido, whereas the replenishment of DA agonists (e.g., levodopa in a patient with Parkinsonism) can elevate libido. Serotonin reuptake inhibitors (SSRIs), a class of antidepressants that cause increased levels of serotonin in the neural junction, are sexually adverse, as seen with the common side effects of reduced libido, as well as, ejaculatory and orgasmic delay (28), the latter effect which is used to treat premature ejaculation. Of the tricyclic antidepressants, amitriptyline, clomipramine, and doxepin appear to have the most negative impact on sexual function, especially orgasm and ejaculation (29). Reducing doses, short drug holidays, or switching to a “sex-friendly antidepressant” such as bupropion, nefazodone, trazodone, or mirtazapine are alternatives (30), but trazodone has been known to cause prolonged nocturnal erection and priapism (31). In the *periphery*, since genital arousal is primarily under parasympathetic control, sympathomimetic drugs cause vascular and smooth muscle constriction, inhibiting genital arousal. Drugs that antagonize cholinergic effects, such as tricyclic and SSRI antidepressants, phenothiazines, and butyrophenones, or those that decrease peripheral vascular resistance and genital blood flow, such as antihypertensives, can cause libido, erection and vaginal lubrication problems, and ejaculation issues (29,32) (Table 16-1). The use of phosphodiesterase V inhibitors (PDE5i’s) can often ameliorate the altered genital arousal side effects of such drugs as SSRIs and thiazide diuretics. PDE5i’s work less well in low testosterone milieus (32–40).

## Aging

Age brings changes to elasticity of tissues, narrowing of vasculature, and decreased neural transmission, resulting in changes to the integrity and capacity of the sexual organs. Postmenopausal women experience less vaginal lubrication and decreased muscle spasm at orgasm. Men may take two to three times as long to achieve an erection, the erection will not be as rigid, and if the erection is lost with ejaculation, it may take even longer to regain it (7). Orgasm may be delayed and ejaculatory fluid volume

**TABLE 16.1** Rehabilitation Medications Affecting Sexual Functioning

Medication/Class	Cause of Sexual Effect (28,29,32–40)	Dysfunction
Antihypertensives	Central sympatholytic/peripheral $\alpha$ -blocker	AD, $\downarrow$ SD, EjD
SSRIs	Sex suppressant, especially orgasm	EjD, $\downarrow$ SD, AD
Anticonvulsants	$\downarrow$ Arousal	AD, $\downarrow$ SD
Opiates, marijuana, antipsychotics	$\downarrow$ Testosterone levels and/or $\uparrow$ prolactin levels: with chronic use, sex suppressant	$\downarrow$ SD, AD, EjD
Antispasmodics	May suppress sexual reflexes	AD, EjD
Antilipidemics	Associated with ED	
Indomethacin	Causing fertility problems	
Gabapentin	Causing variable effects	
Digoxin	$\downarrow$ Testosterone and LH and $\uparrow$ estrogen	$\downarrow$ SD, AD
H2-blockers	Antiandrogen types affect arousal and can cause reversible spermatogenic suppression	$\downarrow$ SD, AD

$\downarrow$ SD, decreased sex drive; AD, arousal dysfunction; EjD, ejaculatory or orgasmic dysfunction.

is reduced with age, likely due to reduced testosterone levels. Once ejaculation or orgasm occurs, penile detumescence and other genital changes occur rapidly and the refractory period is long (even days) in the elderly. Even with cross-cultural factors and medication issues taken into account, the prevalence of most sexual problems tends to increase with age; however, older age, net of other factors, consistently increases the likelihood of more sexual problems among men, but less so for women (the exception is poor lubrication, which is a significant issue for women as they age) (41). In women, sexual pain disorders appear to decline with age (42). Self-esteem may suffer with aging skin changes, weight gain, aches and pains, graying or loss of hair, fatigue, and declining athletic ability. Depression, a factor that blunts almost all aspects of sexual functioning, is far more common in the elderly. Dealing with a disability may lower expectations of both aging partners, but a previous healthy sexual relationship and open communication skills bode well for maintaining sexual intimacy despite health issues (4).

### Impending Mortality

Variable effects on sexuality can be expected with impending death. Some persons lose interest and focus on survival, and others embrace sexuality as a quality of life/intimacy issue that represents the positive aspects of living. Partnership support is obviously critical in this outlook. End stage disabilities and cancer share several assaults on sexuality, including medication effects, fatigue, change of body image with any disfiguring surgery or amputation, altered hormonal status, catheters, stomas, secondary paralysis, and relationship and psychological stress. Often sexual effects of life saving/prolonging procedures and surgery are inadequately discussed before and/or after the procedures, leading to sexual distress.

### Neurological Changes

The advent of noninvasive brain imaging techniques such as PET and fMRI have demonstrated areas in the brain associated with imagery, visual sexual stimulation, arousal, and orgasm

in both sexes (23,26,43). Injuries to these specific brain areas, and to the spinal cord and peripheral nerves innervating and sending sensory information to the cognitive centers, will profoundly affect sexual functioning. Furthermore, the sequela of having a neurological disability that can affect cognitive, motor, sensory, and autonomic functions will have multiple effects on sexuality. Most acquired neurological damage must undergo 2 to 4 years of recovery before the remaining neurological sexual function is known.

### Psychological Factors

Adjusting to disability is a highly unique matter, related to the severity of losses caused by the disability (not just physical, but emotional, relational, and financial), whether depression occurs and/or persists, the presence and strength of support systems, and premorbid personality factors and coping skills. For some persons, sexuality is a highly integral part of their self-esteem and/or self-image, and the disruption occurring with disability can be devastating. Whether the disability occurred acutely or slowly over time can also affect sexual adjustment, since readiness to approach the issue again has to be balanced with other life priorities such as physical recovery or financial losses. Age and sexual experience are critical factors. Willingness to reenter the sexual arena with past or new partners and openness to experiment with a changed body and/or utilize assistive aids takes a certain mindset and readiness. Anxiety can also play a part, resulting in arousal problems or premature ejaculation, and can also decrease interest or orgasmic attainment. Disability and chronic illness can affect both persons of the couple often with reversal of traditional masculine and feminine roles, loss of economic security, caretaking issues that depress sexual attraction, fatigue on the part of both persons, and forced alteration of life goals that may no longer make the couple compatible (40).

### Cardiovascular Factors and Risks

Several studies address the cardiovascular response to sexual activity and the possible risk of an acute cardiac event.

An average peak HR of 110 to 130 bpm and peak systolic BP of 150 to 170 mm Hg was observed during the sexual activities of couples with longstanding relationships (44,45). Generally, the energy requirements during sexual activity do not exceed 4 to 5 METs (46). Furthermore, it was established that walking on a treadmill at 3 miles/hour at a 5% grade or climbing two flights of stairs at a rate of 20 steps in 10 seconds would require equivalent amounts of energy as sexual intercourse (44). This information on the two-flight test, which is equivalent to 6 METs, has been widely used to determine the risk of ischemia and/or safe return to sexual activity after cardiac events. However, even with no underlying cardiac muscle or blood vessel pathology, disordered autonomic control of the heart and/or blood vessels can result in significant alteration of cardiovascular responses during sexual activities. This is especially prominent in individuals with SCI (47), where abnormal autonomic control could result in the onset of autonomic dysreflexia (AD) during sexual activities (especially with ejaculation) and/or continuation of AD after activities (48) (Fig. 16-1). AD is a condition characterized by episodic hypertension, often associated with cardiac arrhythmias (49). Hypertensive crises during the episodes of AD can result in cardiac arrest, retinal or subarachnoid hemorrhages, cerebral

vascular accidents, and death (50). AD symptoms with sexual activity often attenuate with time, but BP elevations can remain deceptively high.

### Bladder and Bowel Concerns

Bladder and bowel issues are one of the most important factors in sexual quality of life in persons with disability (3,51,52), as they influence willingness to be social or to leave the security and privacy of one's home where supplies are located. For some, life can seem dictated by washroom availability. The potential for odor from, or leakage or visibility of, urine or stool collection devices, can affect sexual self-esteem and social comfort, and interfere with the interest of a partner. The time required for a bowel program, for catheterization and/or attendant care, can be one of the main dissuaders from being spontaneous or social, and the risk of incontinence with sexual activity can severely limit sexual expression. To pursue a relationship or sexual partnership, the risk of major embarrassment has to be courageously accepted by the person with a disability. Bladder and bowel management must be assertively pursued to improve body image and independence, even if it means major measures, such as continent urinary diversions (53).

**FIGURE 16-1.** BP and ECG recordings in individuals with C6 ASIA A SCI during VS procedure for sperm retrieval. Prior to VS (Rest, recording 1), there is relative hypotension (69/49 mm Hg) with regular HR of 82 bpm. With initiation of VS, arterial BP gradually increased to 148/105 mm Hg and the patient developed bradycardia (recording 2, HR 60 bpm) suggestive of typical episode of AD. Finally, at the time of ejaculation (recording 3) arterial BP surged to 240/130 mm Hg accompanied with a short period of cardiac arrhythmia. Interesting to mention is that in this case the patient did deny any symptoms typical for AD such as headache, blurred vision, sweating, and piloerection (personal observations).

## Pain Issues

In a survey of patients with chronic pain attending treatment centers, sexual difficulties were found to be twice that of the general population, and these difficulties were not simply related to mood or disability (54). Two types of pain conditions can affect sexuality. Pain localized to the genitals, pelvis, or other sexualized areas can directly interfere with sexual function and motivation, whereas chronic pain conditions can interfere with daily life and indirectly affect sexuality. Chronic pain conditions can result in depression, weight loss or gain, physical deconditioning, and loss of self-image, resulting in decreased mental, physical, and sexual functioning (54). The severity of pain and its location can also have a major role in sexual quality of life. Psychological variables are important and need to be incorporated into therapeutic approaches. Sexual dysfunction was found to be more frequently reported by those with greater disability and depression, shorter pain duration, and infrequent use of coping self-statements (55). With genital pain, because the issues are so complex, multimodal and multidisciplinary intervention is always required (56).

## Fertility Concerns

With any disability, the question of fertility needs to be approached from four directions (57): (a) sexual functioning problems interfering with the ability to enter into the act of intercourse and for men, to ejaculate; (b) hormonal alterations secondary to the condition (i.e., head injury) or treatment (i.e., MS medications, brain irradiation); (c) altered oocyte or sperm quality secondary to the condition or treatment; and (d) inheritable genetic traits (58). In most cases, erection problems in men can be overcome with current available treatments, but ejaculation dysfunction may require sperm retrieval methods such as vibrostimulation (VS) and electroejaculation (EE), or surgical technology where sperm is aspirated from the epididymis or testicle (50). The less invasive VS is quite successful in those men with SCI whose injuries are higher than T10, with the more invasive EE being reserved for VS failures, but EE can also be utilized in conditions such as seminal emission failure secondary to retroperitoneal lymph node dissections for testicular cancer, or ejaculation failure in diabetes (59). Depending on the semen quality and quantity, obtained sperm can be placed in the vagina (intravaginal insemination), prepared and placed in the uterus (intrauterine insemination), or utilized with higher technology such as in vitro fertilization and intracytoplasmic sperm injection (IVF/ICSI). Women may not be able to have sexual intercourse due to a sexual pain disorder or other sexual dysfunction, or if adductor spasm is severe. In men, SCI *per se* negatively reduces sperm motility and increases abnormal morphology likely secondary to abnormalities within the seminal fluid (59). In women with SCI, pregnancy is associated with increased risks and complications such as increased incidence of urinary tract infections, changes in bladder management, increased risk for skin breakdown, difficulty with transfers due to increasing maternal weight, increased risk for deep vein thrombosis, delayed

bowel emptying, pedal edema, vaginal spotting, fatigue, and thrombophlebitis. Special monitoring is necessary during labor and delivery as labor may not be felt or may present differently than in noninjured women, AD can occur, Caesarian sections and vacuum and forcep extractions are more common, and women with SCI also deliver lower birth-weight infants, the etiology of which is not clearly understood (50). Further information can be found in Chapters 72 and 80. Women with other chronic conditions also have to evaluate the safety and capacity to carry a pregnancy to term and undergo delivery.

## SEXUALITY IN SPECIFIC DISABILITIES

### Spinal Cord Injury

SCI has been the most extensively researched (animal and human) disability for understanding sexual neurophysiology and provides an excellent model for the holistic and reintegration approach that comprises sexual rehabilitation (18,40,50,60–63). After complete SCI above the lumbosacral spinal cord center (usually above T10), reflexogenic arousal should be preserved whereas psychogenic arousal will not (due to the lesion interrupting the pathways from the brain to the T10–L2 spinal segment, the level responsible for psychogenic arousal). Conversely, complete lesions interrupting the sacral reflexogenic pathways will result on the reliance of psychogenic arousal to promote genital erection in men and women. Unfortunately, in men with sacral SCI reliant on psychogenic arousal, the stimulation of the hypogastric and sympathetic pathways through mental arousal can trigger unwanted seminal emission and penile detumescence, a frustrating experience. Men and women with varying SCI levels and incompleteness will experience various capacities to tap into their psychogenic or reflexogenic pathways. The degree of preservation of sensation in the T11–L2 dermatomes is helpful in predicting those persons with SCI who are capable of psychogenic arousal (61,62), whereas the presence of a positive bulbocavernosus reflex (BCR) is indicative of an intact sacral reflex, boding well for the reflexogenic arousal capacity. While over ¾ of men with SCI can obtain an erection, firmness and reliability in sexual situations can be a problem. Ejaculatory disorders (primarily anejaculation) are highly prevalent (over 90%) and thus fertility is a major issue for men with SCI (5). Natural ejaculation is most likely to occur in men with incomplete conus medullaris or cauda equina lesions, and least likely in men with complete supraconal lesions (64). However, VS-assisted ejaculation is more reliable in complete supraconal lesions (59). Orgasm is attainable in 40% to 45% of men (most often with ejaculation but not always) (51,61) and approximately 50% of women after SCI (62). Lack of genital sensation, and especially lower motor neuron injury affecting the sacral segments, make it significantly less likely to reach a genitally triggered orgasm (3,25). While sexual satisfaction after injury is lower in both men and women after SCI, pursuing intimacy remains a major quality of life issue for the majority living with SCI (3).

## Multiple Sclerosis

It is estimated that more than 70% of men and women with MS experience some form of sexual dysfunction during their disease (65) even in the absence of severe disability (66,67). Sexual symptomatology can fluctuate with the changing nature and duration of MS, and will depend on the localization of lesions in the spinal cord or brain (43,68–70). Libido problems can be acute or chronic, and are linked to depression, presence of cerebral plaques, and the inability to experience orgasm (72). In ambulatory male patients with MS, 60% had ED, 50% had ejaculatory or orgasmic dysfunction or both, and 40% reduced desire (43). In men, if orgasm can be reached, ejaculatory fluid may flow out by gravity, minutes later. Women with MS report unsatisfactory sexual lives secondary to fatigue (68%), reduced genital sensation (48%), reduced vaginal lubrication and difficulty with arousal (35%), difficulty reaching orgasm and anorgasmia (72%), and sexual pain disorders (28). Furthermore, spasticity, fatigue, changes to genital sensation (71), muscle weakness, fear of fatigue with sexual activity and concerns about continence during sex (72) can affect the ability or willingness to engage in certain sexual acts, especially intercourse. Cognitive changes and psychological impact of the disorder can result in anxiety, depression, poor self-image, and lack of interest in sex in both patient and partner (40).

## Limb Amputation

Sexuality in the amputee population has not attracted researchers' attention since genital sexual function is often preserved (73). However, if the amputation is not traumatic but secondary to diabetes or cancer treatments, there will be added sexual complications from the underlying disorder. The medically indicated loss of a limb can have serious psychosexual impact, as can the surgical procedure itself, and result in perioperative and prosthetic device pain, deformity, phantom limb pain, and inability to perform customary sexual acts. Amputees have to adjust to a different body image, and depression may persist for years (74). Rehabilitative considerations for sexual acts are important, and physiotherapy assessment and education is necessary. Positioning options for sexual intercourse may need to be provided, and while preservation of the knee joint is helpful for balance, positioning with pillows or wedges, or the use of spoon or side-by-side intercourse may be necessary for upper limb or transfemoral amputations (74).

## Parkinson's Disease

Sexual dysfunction is common in Parkinson's disease (PD). At least 75% of women with PD report difficulties with arousal and orgasm; and 50% experience low sexual desire. In men, 70% experience erectile difficulties, 40% have premature ejaculation, and 40% have delayed orgasm (75). Furthermore, bladder and bowel dysfunction that could interfere with sexual activity is prominent in patients with PD compared to controls of the same ages (76). An increase in sexual drive can be experienced with dopaminergic drugs, but often genital sexual dys-

functions can remain, leading to increased sexual frustration for the person with PD. Because of the psychomotor and disinhibiting cognitive changes, partner attraction and caretaker concerns can be an issue.

## Neuromuscular Disorders

Though there is scant literature and research on the sexual consequences of neuromuscular diseases (including myopathies and neurological disorders), it is clear that sexuality is a very important topic for this population and their partners, but it is rarely discussed in medical settings. Sexual dysfunction is usually due to non-genital causes, e.g., physical limitations, privacy, and caregiver issues (60). Since these disorders vary tremendously from a moderate loss of stamina and strength, to life-threatening motor disability including loss of pulmonary capacity, the effect on sexual functioning can vary greatly. Age of onset (childhood or adult) of a neuromuscular disorder and its rate of progression are critical determinants of a patient's sexual practices and problems (77). Amyotrophic lateral sclerosis (ALS) spares sensory and autonomic neurons, maintaining sexual, bladder, and bowel functions while rapidly destroying motor neurons leading to almost total paralysis of the whole body. Sexuality was found to be an important issue, including in persons with ventilator-dependent ALS, and identified sexual problems included decreased libido, passivity of partner, and the patient's own passivity due to physical weakness and body image changes due to ALS (78). Only in late stages did persons with ALS lose sexual desire (79). Factors such as independence in community living, choice of attendant care, and the ability to self-direct one's personal affairs despite severe disability were found to support the high rate of successful marriage in persons with ALS (80).

## Traumatic Brain Injury

Traumatic brain injury (TBI) can have variable effects on sexual function depending on the severity of the injury, the location of the lesion, and whether there are endocrinological disturbances and/or seizures secondary to the brain insult. Unfortunately, TBI often occurs in young persons between the ages of 15 and 24 (81), where sexual potential and experimentation with intimate companionships are at a peak. Decreased desire and arousal disorders are common, whereas hypersexuality and/or sexual deviancy post-brain injury is rare. Hypersexuality is seen in the Kluver-Bucy syndrome (82) and in bilateral thalamic infarction (83). In one study, compared with uninjured controls, men and women with brain injury reported lower energy and low interest in initiating sex (possibly due to decreased levels of testosterone), and difficulties with erection, vaginal dryness causing pain during sexual activities, and orgasm (84). While ED is common, it is variably reported from 10% to 71% (84), and can be organic in nature even if bladder or bowel problems are not evident. TBI will not only affect the cognitive status and personality (e.g., irritability and loss of anger control), but can also affect physical issues such as sensory loss to erogenous areas, paralysis, and/or spasticity. TBI does

not have to be severe in order to develop hypogonadotropic hypogonadism (43). A comprehensive review of brain injury lesions and their sexual sequela can be found in other texts (40,43,85). The problem of “inappropriate behavior” needs to be properly addressed, as it may be the result of a correctable concern (i.e., provision of sexual relief), or of values and beliefs of caregiver versus client (86).

### Stroke

Despite the high incidence and prevalence of stroke, only limited numbers of studies with a small numbers of subjects have addressed issues of sexuality (87). Unfortunately, the real effect of stroke on sexuality is clouded by the fact that most individuals with stroke are elderly, are taking a number of medications that can affect sexuality, and already have a variety of concomitant medical problems that can also impact their sexuality. Men and women who suffer strokes frequently report a decrease in libido, decrease in lubrication and decline in erectile capability in comparison with prestroke, and a decrease in the frequency of sexual activity (88,89). Mutual verbal and nonverbal responsiveness, as well as frequency of caressing and touching with intention of being sexual, can decline (90). This may be due to inhibition or disinterest on the part of the person who had the stroke, but may also be due to reluctance of the partner when unattractive behaviors such as drooling or incontinence are present (89,90). Fortunately, practical guides to resuming activity after stroke are becoming more available (91).

### Coronary Artery Disease

In contrast to stroke, a large body of literature is focused on the impact of cardiac disease on sexual functioning, accompanied by a great imbalance in the attention paid to male as opposed to female sexual dysfunctions following cardiac events. In one study, following a first cardiac event, up to 75% of middle-aged male patients either decreased or stopped sexual activity, and 80% of male patients with congestive heart failure reported either marked problems with or an inability to engage in sex (92). This dramatic decline in sexual activity occurs despite the fact that sexual activity requires fairly low energy expenditures as noted earlier (44). Similar to stroke survivors, the reasons patients and partners give for the decline in intimacy are more complicated than mere loss of interest or an inability to respond, instead they often reflect the multiple preoccupations and stresses of a chronic disease, as well as unwarranted fears of experiencing a heart attack during sex. However, clinical data suggest that sex is a comparatively weak precipitant of acute coronary events, accounting for only 0.5% to 1.0% of all such events (93).

### Pulmonary Disease

Patients with emphysema and chronic bronchitis, or chronic obstructive pulmonary disease (COPD), often have concomitant issues with diabetes mellitus, endocrine abnormalities, cardiac disease, and autonomic nerve dysfunction that can affect sexual functioning, so it is difficult to differentiate those sexual concerns stemming from pulmonary problems alone and those of the comorbidities and their medications used to treat them. However, in COPD, dyspnea leads to diminished

activity tolerance, and since full exhalation is not possible because of pre-existing obstruction, attaining the respiratory rate of 40 to 60 breaths per minute required for sexual activity can be a problem. Partner weight on the chest can also worsen the dyspnea. These stressors, along with fear and anxiety, lead to heightened sympathetic tone, hyperventilation, bronchospasm, coughing and further anxiety, such that a vicious cycle is created (94). Furthermore, testosterone levels are often reduced with chronic hypoxia, which contributes to poor genital arousal capacity. Specific breathing techniques, redirection to sexual practices and positioning to reduce dyspnea, use of inhalers, oxygen or cough drops prior to or during activity, and training with relaxation techniques can assist these couples (40,94).

### Diabetes

Diabetes affects the core physiology of sexual function in both sexes. Small and large vessel disease, peripheral neuropathy, smooth muscle dysfunction in the genitalia, and psychological problems are variably responsible for libido, arousal, and orgasmic difficulties, as well as dyspareunia in women. Whereas the incidence of sexual dysfunction in men with diabetes approaches 50%, it is only slightly lower in diabetic women (28). ED also correlates with poor glycemic control (95), and therefore can be reversible in some cases. There are less frequent effects noted on ejaculation and orgasm, but the slow and steady onset of retrograde ejaculation is a known complication and can affect fertility (96). In both genders, neurovascular pathology can affect genital sensation, thus impairing orgasm (97). A significant positive association is found between the number of diabetic complications and the number of sexual complaints, and in women with Type 1 diabetes, sexual dysfunction is also related to depression and the quality of the relationship with the partner (98). Sexual dissatisfaction is further correlated with relationship and self-esteem problems, secondary medical conditions such as stroke or chronic renal failure (CRF), and reactions to catastrophic complications such as limb amputation (96).

### Chronic Renal Failure

The comorbid etiologies of chronic renal failure (CRF) are responsible for ED in men, menstrual abnormalities in women, and the decreased libido and fertility in both sexes (28). Physiologic changes from uremia and the disturbances in the hypothalamic-pituitary-gonadal axis can occur before and/or after the initiation of hemodialysis or continuous ambulatory peritoneal dialysis. Central disturbances appear more prominent in uremic women, whereas the more subtle disturbances in the hypothalamic-pituitary-gonadal axis and impaired gonadal function are the main issues in men (99). Hyperprolactinemia in both men and women results in decreased libido, decreased frequency of sexual intercourse rates, orgasmic difficulties, and abbreviated longevity of sexual activity between couples (100).

### Arthritis and Connective Tissue Diseases

Individuals with osteoarthritis and rheumatoid arthritis have many assaults on their sexuality, centered around pain, joint

stiffness and/or deformity, weakness, and depression. Poor hand function, loss of range of motion to the hips, adduction difficulties, knee pain, and back spasm can affect the mechanics for sexual acts (including pelvic thrusting), and positioning. Use of corticosteroids for treatment of rheumatoid disease can cause acne, truncal obesity, hirsutism, steroid facies (moon face), and other features that can affect sexual self-esteem. Other immunosuppressant medications can cause bladder problems and oral-genital ulceration (101). Approximately one third of patients with ankylosing spondylitis have some degree of sexual dysfunction, especially those with depression and joint mobility issues (101,102) and a significant degree of morning stiffness (> 4 hours) (103). Persons with systemic lupus erythematosus (SLE) have greater impairment with sexual dysfunction the greater the severity of disease (101). In women with systemic sclerosis, vaginal involvement, skin tightness, and muscle weakness affect sexual function, and decreased orgasmic function is prominent (104). Compared to healthy normal controls, women with fibromyalgia have similar overall sexual function, but have more problems with sexual desire, satisfaction, pain, and insensitivity of their genitals around the times of sexual activity (105). Another study in women with fibromyalgia showed coexistent major depression having no additional negative effect on sexual function (106).

## SEXUAL REHABILITATION FRAMEWORK

Failing to address sexuality in a rehabilitation setting is no longer an option. With clear evidence that sexuality is very important in this population, and with patient-centered care, professional discomfort about discussing such issues should be secondary to the need to have patient's sexual concerns addressed. A basic screening question such as "Many persons with [your disability/chronic illness] experience sexual concerns [examples can be given]. Do you have any concerns you would like to address?" allows the door to the topic to be opened, even if the person with the disability/chronic illness is not acutely in distress. Asking whether someone is "currently sexually active" may not be as helpful a screening question, since it assumes a willing partner is available, and sexual concerns can exist from solo or partnered activities. Addressing sexuality confirms that the issue is acceptable and medically legitimate, and allows freedom of choice to pursue therapeutic intervention.

One does not have to be a sexual medicine expert to take a sexual history. Below is a user-friendly framework adapted from Szasz (107) for clinicians to use, since it allows for an intuitive process to assess and manage patients. Patients are assessed holistically with regard to their disability/chronic illness since not all questions are genitally focused. A more detailed version is available (4):

1. Sexual interest (biological urge combined with the motivation and/or wish to be sexual)
2. Sexual response (mental and genital arousal, ejaculation in men, ability to attain orgasm and orgasmic quality)

3. Changes to genital sensation or other erogenous zones (loss of erotic zone sensitivity or hypersensitivities in specific areas, etc.)
4. Changes to motor function (hand function, balance, ability to transfer to a bed, hold a partner, etc.)
5. Bladder and bowel issues (management strategies, concerns with continence during social and sexual activities, and social implications)
6. Factors associated with the condition (medication effects, alteration in hormone status, pain, fatigue, AD, anemia, etc.)
7. Practical use of contraception, concerns about fertility, pregnancy, delivery
8. Parenting issues specific to the disability or illness
9. Relationship and partnership issues (the sexual context within which the person lives)
10. Sexual self-esteem and self-view issues (physical presentation, disfigurement, masculinity/femininity, changes in gender role, etc.)

The physical examination and any accompanying blood-work should appropriately address the issues elicited above. Serum-free or bioavailable testosterone levels should be checked in persons with head injury, especially if they have noticed a change in sexual desire. It is important to assess genital sensation (light touch and pinprick), rectal tone, voluntary anal contraction, and the presence or absence of a BCR. As noted earlier the BCR signifies an intact sacral reflex and the probability of reflexogenic arousal and ejaculation capacity. Detection of pinprick sensation around the glans penis or clitoris with the combined ability to voluntarily contract the anal opening is helpful in assessing the capacity for genitally triggered orgasm in persons with neurologic changes (with the exception of complete SCI) (107).

## CURRENT THERAPIES FOR SEXUAL DYSFUNCTIONS

Sexual rehabilitation is multidisciplinary. While physician assessment must include inquiring about sexual concerns (as patients often do not bring up the topic), rehabilitation therapists, nurses, social workers and others may be asked questions regarding sexuality from patients who feel particularly comfortable with that particular clinician, or who gather the courage. If the inquiry may seem misplaced or inappropriate in some cases, a simple reflective "It seems you have some concerns about your sexual functioning, is that the case?" can put professionalism back into the situation without deflecting the legitimacy of the patient's concern. Nonjudgmentally acknowledging the patient as a sexual human being, providing basic support, discussing options, or arranging a referral, can go a long way to alleviate patient anxiety. Obtaining assistance related to physical limitations for self and partner pleasuring may require the persistence of occupational or physical therapists, sexual health

counselors, and even surgeons. Other patient suggestions include

1. Encourage sexual activity when rested and plan sexual occasions to avoid fatigue. Expectation of spontaneity may no longer be realistic, but the event can be special in its anticipation. Try and create a space or bedroom free from rehabilitative paraphernalia to create a conducive environment separate from medical intervention.
2. Experiment, alone or with a partner, with positioning and cushioning to best allow for ease of breathing, pain reduction, reduction of bladder or bowel pressure, and balance.
3. Use bladder and bowel strategies to the best advantage, such as fluid reduction, voiding or catheterization prior to activity, and regulation of bowel routines.
4. Be strategic with the use of medications to maximize pain relief and relaxation, and encourage trials of medicines for sexual activity and use of sexual aids on their own, before introducing it into a partner situation.
5. Protect privacy, both psychological and physical (this includes the provision for self-stimulation in institutionalized settings).
6. Foster patient independence around sexual issues. This would include such things as choosing a respectful caregiver, or setting up sexual aids that can be used alone. Resist overprotectiveness with young persons or those with severe disabilities around sexual issues if they are capable of personal choice (27).
7. Be cognizant of the factors affecting sexual interest in both partners, such as depression, feeling “less” like a man or woman due to changed roles, loss of financial earning power, and changed sexual motivation if partners are also the primary caregiver.
8. Introduce medical therapeutic options once physiological maximization has occurred (59).

### Medical Options for Sexual Difficulties

Talk-oriented therapy is a critical component in the proper treatment of all sexual disorders, as the mind-body interaction cannot be separated into distinct entities. Reintegration of body image and formulations of new sensory “body maps” can happen alone or with a partner, but the presence of a long-term trusted partner appears key to maximally discovering sexual potential (108). While sex therapy *per se* is beyond the scope of this chapter, psychological and relationship issues must be addressed if medical therapy is to be productive (4). In couple relationships, open communication around sexual wants, needs, and abilities, is even more critical when couples are faced with disability or illness. Persons without partners must also have sexual needs addressed, including the use of masturbation aids, as self-stimulation may be an important source of joy for this person (27).

### Sexual Drive Problems

Changes to sexual drive involve complex biopsychosocial issues (4). Medically it is imperative not to miss any biologically reversible factors, such as hypogonadism, hypothyroidism, untreated

depression, and inadequate pain management. If possible, medications affecting drive should be altered or eliminated. It is also critical to address issues that affect sexual willingness and/or motivation, such as those noted in the previous suggestions. Ongoing hypoactive desire problems need specialist assessment and management. Hypersexuality is more difficult to manage, especially if cognitive behavioral therapy is not possible; in some cases, use of SSRIs, antiandrogens, or DA antagonists can be tried (43).

### Erection Enhancement

Oral medications that indirectly relax the penile smooth muscle and enhance an erection attained from psychogenic sexual stimulation are the first-line therapy and have been available for the last 10 years. The PDE5i's, including Viagra (sildenafil), Levitra (vardenafil), and Cialis (tadalafil), work very well when there is a source of nitric oxide (NO) from either intact peripheral nerves (stimulated by intact arousal pathways) or healthy endothelial lining. PDE5i's, therefore, do not work as well when there is poor neuronal or endothelial NO sources, such as in diabetes, atherosclerosis, hypertension, peripheral nerve injury, or autonomic neuropathy. In these cases, adjusting the medication to higher on demand dosing, or even using a lower dose of PDE5i on a daily basis, with or without additional PDE5i on demand, may prove beneficial. In other cases, where the PDE5i are more reliably effective, that is, ED secondary to SCI (50), psychogenic ED, and ED secondary to antidepressant use (109), lower dose on demand dosing is likely adequate since the endothelial and nerve generation of NO is presumed to be better. Since there is a slight BP lowering effect of the PDE5i, a lower starting dose of on demand PDE5i should be used in men at risk for hypotension. Lower doses should also be started in men with significant renal or hepatic impairment, or who may be taking drugs that increase the serum levels of PDE5i, such as antiretrovirals. PDE5i should be used with caution in patients with cardiac failure, within 6 months of acute myocardial infarction or stroke, and in patients with unstable angina pectoris. Coadministration of PDE5i with organic nitrates is contraindicated due to compounded lowering of BP. Relative contraindications include uncontrolled hypertension and impaired cardiac reserve, or symptomatic hypotension (such as in tetraplegia). There is relatively little interaction with other drugs, and the PDE5i's have proven safe with no increased incidence of cardiovascular events or stroke. PDE5i have potentially beneficial effects on other body systems primarily through their smooth muscle relaxant effect. Some improvements have been seen with lower urinary tract symptoms and benign prostatic hyperplasia, and PDE5i may also be beneficial as well in vasoconstrictive disorders, may be protective against neurodegeneration and memory impairment, and are approved for use in pulmonary hypertension (109,110).

Injectable medication which directly relaxes the penile smooth muscle to create an erection is administered through intracavernosal injections (ICI) or penile injections. Prostaglandin E1 (PGE1), also called alprostadil (pharmacy compounded or commercially available as Caverject), can be injected into the side of the penis. PGE1 is most commonly used for ICI due to its

higher safety profile, but other combinations typically of PGE1, papaverine and phentolamine, and occasionally atropine, can be compounded (111). ICI is the most effective treatment for ED, but proper technique and dosing must be taught. Men with neurological impairment require lower doses as they are at risk for prolonged erections or even priapism. Higher doses may be necessary in those with primarily vascular ED, such as diabetics and hypertensive patients. Good eyesight and adequate steady hand function is required for ICI, unless a needle injector is used or the partner agrees to administer ICI. Topical alprostadil is currently being investigated (112). An intraurethral preparation of PGE1 (MUSE) is available (113), but is less effective than ICI, especially in SCI patients (114).

Mechanical methods such as vacuum devices and penile rings are an effective nonmedicinal option but require some dexterity. After all reversible erection enhancement methods noted above have been exhausted, surgical implantation of a penile prosthesis can be considered, but since the cavernosal tissue is destroyed during placement of the implants, oral medications and ICI will no longer be effective. This permanency, plus the risks of surgery and infection, makes the placement of penile implants worthy of proper assessment (115).

Partner acceptance and cost also influence the choice of which ED therapy to use. Practical issues such as visual acuity, hand function, bladder management, whether the ED option can be performed independently or requires the assistance of a partner or caregiver, must be taken into consideration.

### Male Ejaculatory and Orgasmic Difficulties

Ejaculatory problems after injury or chronic illness (like diabetes) are most often a result of neurological changes as opposed to psychological causes. If the nerves responsible for ejaculation have been disrupted, few options are available to trigger ejaculation. Sometimes high dose pseudoephedrine can encourage seminal emission if sympathetic nerves have been compromised or if retrograde ejaculation is present (5,116–118). Obtaining an antegrade ejaculation for fertility purposes can be accomplished by functional or operative sperm retrieval methods. Those men who acquire secondary rapid or spontaneous ejaculation after spinal cord impairment may not be helped by the traditional use of SSRI medications used to treat premature ejaculation but slight improvement has been noted with phenoxybenzamine, terazosin, or prazosin (119). Age and neurological disability can cause orgasmic delay, but it is important to remind men that an erection is not required to reach orgasm. Testosterone replacement in hypogonadal males and selection of sex-friendly antidepressant options in depressed men can be tried to assist delayed orgasm. The use of VS, especially when the vibrating attachment is cup shaped to enclose the glans penis, can assist with orgasmic attainment, even in neurologically intact men.

For fertility purposes, VS used in men with SCI involves the use of specialized powerful vibrators made with adjustable frequencies and amplitudes such that the uninjured sacral ejaculatory reflex can be triggered by placing the vibrator, or sometimes two in a sandwiching technique, on the glans penis.

VS can often trigger AD, so it must initially be done in a clinic setting with experienced clinicians. If VS fails to elicit ejaculation, then EE can be tried. EE consists of placement of an electrical probe through the anal opening to approximate the location of the periprostatic nerves. Once current is applied, seminal emission is evoked. If there is genital sensory sparing, an incomplete injury or a low SCI, anesthesia may be required. Depending on the cost-benefit ratio of the patient's health care benefits and the level of injury, it may be more efficient to do operative extraction, such as percutaneous epididymal sperm aspiration or testicular sperm extraction. However, VS and EE often provide enough sperm to allow the option of lower technologies such as intravaginal or intrauterine insemination, whereas utilization of operative techniques and the removal of only a few spermatozoa commits the partner of the man to more elaborate and expensive IVF/ICSI. Decisions on fertility technologies are also based on sperm quality, female factors such as age and tubal patency, and cost. In general, the higher the technology, the higher the chance of pregnancy per attempt.

### Female Arousal and Orgasmic Difficulties

In contrast to treatments for men with arousal difficulties, there are no approved medications for these sexual difficulties in women. However, clitoral cavernosal tissue responds as male cavernosal tissue does to PDE5i (especially in premenopausal women), but in healthy women without sexual dysfunction, it results only in enhancing vaginal engorgement during erotic stimuli but not in subjective sexual arousal (23). Some women, however, may benefit from a trial of lower dose PDE5i (120). Minor increases in vaginal lubrication were noted in randomized trials of sildenafil in women with SCI (63) and MS (121). Since direct clitoral stimulation has traditionally been the most effective method of attaining orgasm in women, VS on or near the clitoris may trigger the orgasmic reflex in women with genital sensory alterations. Some women with SCI have found vibration intravaginally or on the cervix to be more effective (122) than clitoral stimulation, but in any case, more prolonged stimulation is usually required compared to preinjury (62). The EROS-Clitoral Therapy Device (CTD), a vacuum device inducing clitoral vascular engorgement, is the only cleared-to-market device available by prescription to treat female sexual dysfunction, and it may prove to be of benefit in increasing orgasmic responses in women with altered pelvic neurophysiology (such as SCI) or with arterial insufficiency (25,123). Theoretically, initiating the BCR reflex and vasocongestion may also improve sensory awareness in women with some pelvic floor sensory preservation. In addition, by strengthening the pelvic floor, VS and/or CTD may prove helpful with urinary incontinence in women with disabilities, further enhancing their sexual self-esteem, but further trials need to be done.

### Nongenital Orgasmic Options

In spite of high arousal, orgasmic experiences can still be elusive to many persons with neurological-related disabilities. For men and women with SCI, the process of learning to enhance one's sexual responsiveness increases with time, positive

partner sexual experience, emotional intimacy, and general open-mindedness (108). The philosophies of mindfulness and Tantric sexual practices, with their emphasis on total body stimulation, relaxation, and mind transcendence, have been particularly useful adjuncts for enhancing sexuality and the learned ability to achieve non-genital orgasm.

## CONCLUSIONS

Sexual dysfunction is highly prevalent in the disability and chronic illness population. For many persons living with a disability, sexuality is a very important quality of life issue, and needs to be respected and treated as a legitimate medical concern. For rehabilitative clinicians, it is critical that specific sexual dysfunctions (sexual interest, arousal, ejaculation, and orgasm) not only be delineated but also be placed within the sexual, relationship, and disability-related contexts for treatment strategies to be successful. The use of a 10-point, user-friendly sexual rehabilitation framework can assist the rehabilitative clinician to approach, assess, and even manage the sexual concerns of their clients. The key to successful sexual rehabilitation is being physically and mentally proactive during recovery, to optimize physiological potential before adding therapies, to adapt if necessary, and to be open to new experiences (59). This may range from simple strategies such as the use of PDE5i, to enhancing genital stimulation with assistive devices in order to reinforce former sexual pathways and reflexes, to learning how to utilize nongenital sensate areas for sexual arousal and even orgasm. There may even be a role for pelvic electrostimulation (124) or neuromodulation with sacral implants (125) in persons with neurological impairment in the future.

Sexuality is an integral and meaningful part of being human. Embracing sexual rehabilitation with curiosity and respect is an essential part of comprehensive rehabilitation.

## ACKNOWLEDGMENTS

The authors would like to express their appreciation for the support from ICORD, the Neurotrauma/Rick Hansen Foundation, Heart and Stroke Foundation, Canadian Institutes of Health Research, Christopher and Dana Reeve Foundation, Disabilities Health Research Network, and to all the colleagues and patients who have taught them the art and science of sexual rehabilitation.

# Vocational Rehabilitation, Independent Living, and Consumerism

## INTRODUCTION

According to the latest Harris poll of Americans with disabilities in 2004, approximately two thirds of working-age people with disabilities are unemployed (1). Other survey data indicate that, of those individuals who are unemployed, the vast majority (two out of three) wanted to work (2). Work plays a central role in life and is a common source of self-identify and financial independence in American society (3). Since its beginning, a major goal of rehabilitation in the United States has been to help people with disabilities become productive members of society through the activity of holding a job. Vocational rehabilitation (VR) programs have been specifically designed to promote work opportunities for people with disabilities. Historically, the focus of VR services has been to assist persons with disabilities who have vocational potential. It was not until 1978 that legislation defining VR services also included provision of services for individuals without clear vocational goals (4). Title VII, Comprehensive Services for Independent Living (IL), an amendment to the Rehabilitation Act of 1973 (PL 93-112), authorizes services for people with severe disabilities, those who require multiple services over an extended period of time and persons whose disability prevents them from working or participating in other major life activities (5).

Although VR and IL are comprised in the same legislation, they have not always worked in tandem, as VR professionals have tended to view consumers of IL services as being unable to achieve gainful employment and therefore not likely to benefit from the VR program (4). In recent years, however, the goals and principles of VR and IL have begun to converge and are likely to continue to do so, especially as newer understandings of rehabilitation and disability become more widely accepted with the growing international impact of the International Classification of Functioning, Disability and Health (ICF). The ICF, which is described more fully in Chapter 19 of this volume, was endorsed by the World Health Organization (WHO) in 2001 and provides a new framework for understanding health and health-related conditions (6). The ICF conceptual model provides a holistic perspective of health that is consistent with contemporary rehabilitation philosophy, in which disability is seen as a consequence of the interaction of the person with the environment (7). In a further development of the ICF, the Physical

and Rehabilitation Medicine section of the European Union of Medical Specialists has recently adopted the ICF conceptual model, in which rehabilitation is understood as a health strategy to help people attain optimal functioning in their interaction with the environment (8,9). Within this model, individuals do not “have” disabilities; rather, they are “people with health conditions experiencing or likely to experience disability” (8). The United Nations Convention on the Rights of Persons with Disabilities has also endorsed an understanding of disability consistent with the ICF model, stating, “disability results from the interaction between persons with impairments and attitudinal and environmental barriers that hinders their full and effective participation in society on an equal basis with others,” including maximum independence and the right to work (10).

For the sake of clarity, terminology such as “persons with disability” is used in this chapter to refer to individuals with a health condition who are experiencing or likely to experience disability. This usage is in no way intended to imply that disability is an attribute of the person; rather, it is understood that disability is a consequence of the interaction between the person with the health condition and the environment.

This chapter provides an overview of both the VR and IL programs in the United States, including the legislative history and purpose of VR and IL services and the differences between these two service paradigms. The authors describe VR program settings and staff, as well as the services that help individuals with disabilities achieve their goals. This chapter also provides a brief review of key research findings that document the effectiveness of VR services and implications for practice.

## PURPOSE AND CHARACTERISTICS OF VR AND IL SERVICES

### Vocational Rehabilitation

The primary purpose of VR has been to help people with disabilities prepare for and obtain gainful employment, usually through competitive employment (e.g., paid work). VR programs provide rehabilitation services designed to maximize independence and employment and to promote full integration and participation in society (11). Rehabilitation

counselors work with individuals who have a wide range of disabilities. These include physical disabilities, such as spinal cord injury, stroke, arthritis, multiple sclerosis, congenital or orthopedic difficulties, chronic pain, or amputations; cognitive disabilities, such as traumatic brain injury (TBI), organic brain syndromes, developmental and learning disabilities; and psychiatric disorders, including major depression, bipolar disorder, and schizophrenia (5).

VR services may be provided in a variety of settings, including the state-federal VR program (a public agency under the U.S. Department of Education), private, non-profit community-based programs (e.g., Goodwill Industries, Easter Seals), rehabilitation hospitals, Veterans Administration system, for-profit rehabilitation firms, psychiatric rehabilitation programs, insurance companies, and employer disability management programs (12). Within the state-federal system, the VR process involves a collaborative relationship in which the rehabilitation counselor and individual with a disability work together to identify a feasible vocational goal and the services needed to achieve employment. This process generally involves: (a) individual assessment and planning, which may include interviewing, paper-and-pencil tests, and performance evaluation in real or simulated work situations; (b) comprehensive services, which may include counseling, education, vocational training, physical therapy, speech therapy, and assistive technology (AT); and (c) job placement, which may include on-the-job training or job trials, job development, job search training, supported employment, placement in permanent employment, and postemployment services. Private rehabilitation companies that work with individuals who have work-related disabilities provide or plan services such as vocational assessment, work capacity evaluation, job analysis, work hardening and reconditioning, vocational training, job accommodations, job-seeking skills, job placement, and employer development.

In the state-federal VR program, the service provision plan is formalized with an Individualized Plan for Employment (IPE), which is jointly developed by the individual and counselor. Once job placement has been achieved, follow-up services are continued for a minimum of 90 days to provide support and consultation to the new employee and to his or her employer. This helps to ensure that the employment situation is working out satisfactorily for all parties (5).

### Independent Living

Living independently with a severe disability in a physical and social world that is often less than accommodating presents a lifetime of challenges. Attention to individual needs also is critical, as the impact of a severe disability may change at different life stages or in varying situations. For example, an individual who is relatively unhampered by disability in one area of life, or during one stage of development, may at another time or under different circumstances be completely overwhelmed by any one of the myriad challenges presented by a severe disability (5). The overriding goal of IL is the full inclusion and participation of individuals with disability in society.

IL programs are designed “to maximize the leadership, empowerment, independence, and productivity of individuals with disabilities and to integrate these individuals into the mainstream of American society” (13). IL services are most often provided by a national network of approximately 500 Independent Living Centers (ILCs, also known as Centers for Independent Living) across the country (14). In contrast to the public state-federal VR program, ILCs are private, nonprofit, community-based organizations that are controlled by consumers to provide services and advocacy by and for persons with all types of disabilities. ILCs are not residential programs per se; rather, they help individuals identify and achieve IL goals. In recent years, IL services have been increasingly recognized as being complementary to traditional VR (4). Due to medical advances, many persons with severe disabilities in the 1960s who only had hope for IL, now are very employable. Thus, IL and VR are continuous elements of the larger rehabilitation process. While VR programs focus specifically on achieving employment-related goals, IL programs provide services that enable persons with severe disabilities to gain more autonomy in their lives, such as IL skills training, peer counseling (e.g., assistance with coping techniques), advocacy, and information and referral services. Their goal is to help individuals with disabilities to achieve their maximum potential within their communities and family units.

ILCs serve as strong advocates for people with disabilities and address an array of national, state, and local issues. They strive to increase both physical and programmatic access to housing, employment, transportation, communities, recreational facilities, and social and health services. An IL program is a community-based program with substantial consumer involvement that provides direct or indirect services (through referral) for people with severe disabilities. Services are often provided by individuals with disabilities. In fact, the majority of ILC personnel must have disabilities to ensure that the rights and needs of persons with disabilities are being addressed appropriately. For example, a consumer with a recent spinal cord injury may be counseled by a seasoned one. Services typically include housing information, attendant care, reading or interpreting, and information about other goods and services necessary for IL. They may also include transportation, peer counseling, advocacy or political action, training in IL skills, equipment maintenance and repair such as wheelchair, and social and recreational services. VR programs may provide these services, but on a limited basis as a secondary or supplementary means of achieving the primary vocational objective. Rather, VR programs refer consumers for these services to the ILCs, as stipulated in Title VII of the 1998 Amendments to the Rehabilitation Act (4).

The VR and the IL paradigm share a consumer-centered approach, but they have different goals. In the VR process, client characteristics, the nature and extent of functional limitations, socioeconomic factors, and other factors are carefully assessed. This information is then reviewed by the counselor and consumer to develop a vocational goal and plan for employment. VR has been criticized by many in the disability rights movement as being disempowering to people with disabilities due to

its focus on providing services designed to “fix” the individual, rather than eliminate societal and environmental barriers that magnify or even create disability (15). The IL movement, in contrast, played a significant role in recognizing disability as being the consequence of external barriers, rather than a “problem” within the individual (16). In the IL process, the concept of independence is subject to various definitions, depending on the unique need and desires of the individual. Success is defined through maximizing self-sufficiency to the greatest extent possible for as long as possible, with an emphasis on consumer self-direction (17). The individual may be independent in some life situations but relatively “dependent” in other life situations in terms of the level of services needed. Within IL, self-determination is the guiding principle; autonomy and level of independence may vary, depending on one’s needs, but the individual maintains as much control as possible in decision making (18). For example, a person with quadriplegia may be able to independently perform tasks at work (e.g., by using a voice recognition program on a computer to compensate for upper mobility limitations) but need more extensive assistance from a personal attendant in performing activities of daily living (ADL) at home. Though dependent in ADL, the person maintains self-determination.

In order to be considered eligible for VR services, the consumer must have a disability that presents a significant barrier to employment and have a feasible vocational goal (4,11). Assessment is an important part of the VR process and is a required initial step to determine if the individual is eligible for services. Once eligibility is determined, assessment is essential to understanding the functional impact of disability on the consumer. Based on results of the assessment, the rehabilitation counselor and consumer identify a vocational objective and begin planning services needed to attain that objective.

IL services, on the other hand, acknowledge the effect of disability on the client, but do not require a thorough analysis of the client, nor the disability, as a prerequisite to the provision

of services. In addition, IL services are totally separate from a consumer’s eligibility for VR services. For example, a consumer may not desire to seek employment or VR services but be able to access IL services. The success of IL programs depends on the people and resources in the community for direction and support. Consumer involvement is key and is assured through the governance structure of ILCs, which must be managed by persons with disabilities; in addition, the ILCs must ensure that a majority of the staff, including those responsible for decision making, as well as the governing Board, are persons with disabilities (19). IL services are aimed at addressing personal and environmental difficulties. In general, research has outlined the following areas for IL programs to address: self-image, well-being, functional limitations, health behaviors, interpersonal skills, and environmental barriers the system level (e.g., regulations, physical access) and within community (e.g., medical providers, social and family support). The appropriateness of IL services is based on the rights of people with disabilities for dignity, freedom, and control of their destiny. A major emphasis is that services assist with modifying the environment, not the person (4). Table 17-1 highlights some of the differences between VR services in the state-federal system and IL services provided by ILCs.

Consumer sovereignty and empowerment have always been the underpinnings of the IL movement. Persons with disabilities encounter an array of both physical and social discrimination. Empowerment is needed to battle discrimination in housing, employment, education, poverty, and social isolation (15). Empowerment is a form of self-determination where people with disabilities, via advocacy (self or institutional) have a right to determine their destiny. The Rehabilitation Act Amendments of 1998 also formalized consumer choice in the VR process and planning. *Consumer sovereignty*, sometimes referred as consumer involvement, asserts that people with disabilities can best judge their own interests and should ultimately determine what services are provided to them (16). This

**TABLE 17.1 VR and IL Services**

State-Federal Vocational Rehabilitation	Independent Living Centers
Public agency	Private, nonprofit community-based program managed by consumers
Assessment of functional impact of disability is required to determine eligibility for services	Assessment is not required to be eligible for services
Formal service plan (IPE)	No stringently defined service plan
Counselor and consumer work in partnership; must mutually agree on goals and services	Services are directed by consumers
Primary goal is gainful employment	Primary goals are related to IL, as defined by each consumer
Services provided by rehabilitation counselor	Services provided by individuals with disabilities
Consumer-centered	Consumer-centered
Employment is criterion of success	Maximized self-sufficiency is a criterion of success
Refer consumers to ILCs for IL skills training	Provide IL skills training
Major services are directed to the goal of achieving an employment outcome	Advocacy is a major service
Focus on employment-related goals	Focus on improved autonomy

current rise of consumerism directly challenges the traditional service delivery system. There has been a gradual de-emphasis on professional decision making with respect to case planning; accordingly, service provision plans are now drawn up jointly by the individual with the disability along with his or her counselor. Because of the increased awareness created by advocacy skills training at ILCs, many people with disabilities are better informed about their benefits and the regulations of the agencies with which they must deal (20).

## LEGISLATIVE HISTORY

World Wars I and II as well as an array of legislation since the early 20th century have had a significant impact on VR programs and the IL movement (4). Refer to Table 17-2 for a summary

of VR's legislative history. The United State's VR program began in 1918 with the passage of the Soldiers' Rehabilitation Act. The Federal Board for Vocational Education, established in 1917 by the Smith-Hughes Act (PL 65-178), was authorized to create VR programs for veterans with disabilities and the U.S. Department of Labor's task was to locate employment for these individuals (11). The Smith-Fess Act of 1920, vocational rehabilitation legislation, was then passed to serve civilians with physical disabilities who were either totally or partially incapable of remunerative employment. State-federal fund matching was used for services, which included vocational guidance, vocational education, occupational adjustment, and placement. Although physical restoration was not emphasized, a prosthetic device would be provided if it was necessary for the person with a disability to complete vocational training (4). The 1920 bill had to be reauthorized every few years and

**TABLE 17.2** Legislative Highlights of VR and IL Programs

1917	Smith-Hughes Act: Established Federal Board for Vocational Education.
1918	Soldier's Rehabilitation Act: Created VR programs for disabled veterans.
1920	Smith-Fess (Civilian Rehabilitation Act): Established civilian rehabilitation programs.
1935	Social Security Act: VR became permanent federal program.
1936	Randolph Sheppard Act: Allowed blind individuals to operate vending stands on federal property.
1938	Wagner-O'Day Act: Required federal government to purchase products from workshops for the blind.
1943	Vocational Rehabilitation Act Amendments: Eligibility expanded to include people with emotional disturbance and developmental disabilities; medical services and income maintenance programs.
1944	The Serviceman's Readjustment Act: Tuition and stipends for returning WWII veterans.
1954	Vocational Rehabilitation Act Amendment: Authorized federal funds to build and expand rehabilitation facilities; training grants to educational institutions for rehabilitation professionals.
1965	Vocational Rehabilitation Act Amendment: Expanded federal-state funding ratio; included "behavior disorder" as new category (but dropped in Rehabilitation Act of 1973).
1973	Rehabilitation Act, Title V: Creation of Individualized Written Rehabilitation Plan (now IPE) and consumer grievance procedures. Title V guaranteed nondiscrimination against people with disabilities.
1974	Rehabilitation Act Amendments: Gave broader definition of "handicapped" emphasizing limitation in major life activities, not only employment.
1978	Title VII of the Rehabilitation Act Amendments—Comprehensive Services for Independent Living: Authorized grants to organizations receiving federal funds to provide IL services to those with little potential for employment.
1986	Rehabilitation Act Amendments: Authorized supported employment services to individuals who could not be placed in competitive employment; increased use of rehabilitation engineering services.
1990	Americans with Disabilities Act: Prohibited discrimination against people with disabilities in employment, public services, public transportation, public accommodation and telecommunication.
1992	Rehabilitation Act Amendments: Emphasized consumer involvement in the development of rehabilitation plans; mandated state rehabilitation agencies establish Rehabilitation Advisory Councils.
1996	Telecommunications Act: Mandated that telecommunications services and equipment be designed and fabricated to be accessible to people with disabilities.
1998	Assistive Technology Act: Provided states funding to develop and expand consumer-responsive technology programs for people with disabilities.
1998	Workforce Investment Act and Rehabilitation Act Amendments: "One-stop" shopping for employment services; emphasized consumer role in service selection and access to information.
1999	Ticket to Work Incentive Improvement Act: Provides SSI and SSDI beneficiaries a "ticket" to purchase VR services from employment network of their choosing.
2001	New Freedom Initiative and Executive Order 13217: Nationwide effort to eliminate barriers to community participation of people with disabilities; six federal agencies directed to review their policies in accordance with new emphasis on community access.
2008	Americans with Disabilities Amendments Act: Includes major life activities such as bending; major body functions are modified (e.g., digestive, bowel); and mitigating factors, not including glasses, will not be viewed when determining disability status.

consequently was frequently in jeopardy of being discontinued. Fortunately, the groundbreaking Social Security Act of 1935 included unemployment compensation, old age insurance, aid to dependent children, maternal and child health services, as well as other important programs. In addition, the VR program was made permanent so that an act of Congress would be required to dismantle the VR system. Similar to the veterans' rehabilitation program, federal monitoring of civilian rehabilitation had become the duty of the Federal Board for Vocational Education. The Randolph-Sheppard Act of 1936 and Wagner-O'Day Act of 1938 provided opportunities for individuals with visual impairment to operate vending stands on federal property and required the federal government to purchase certain products from workshops for the blind, respectively (4).

Between 1920 and 1943, VR provided services to only those with physical disabilities. The Barden-Lafollette Act of 1943 expanded services to individuals with mental retardation, mental illness, and blindness. World War II was monumental in changing the civilians' and veteran rehabilitation systems. During the wartime industrial labor shortage, persons with disabilities demonstrated their ability to work. Furthermore, medical advances, such as the development of antibiotic medications, meant that many more military persons were able to survive. In fact, the board of physical medicine was established within the AMA at this time. The New York University medical school, under the leadership of Dr. Howard Rusk, established the first department of physical medicine (4). The Servicemen's Readjustment Act (PL 73-346) of 1944, known as the "GI Bill of Rights," guaranteed up to 4 years of tuition and a stipend for living expenses for returning veterans, whether disabled or not. Between 1943 and 1953, over 600,000 World War II veterans obtained VR services while another 8 million took advantage of the GI Bill.

The Vocational Rehabilitation Act Amendment of 1954 (PL 83-565) laid the groundwork for a tremendous expansion of the rehabilitation programs. Important facets of this legislation included authorization for the use of federal funds to build and expand rehabilitation facilities, authorization of training grants to institutions for the education of new rehabilitation professionals, and extensive funding for research and demonstration projects to improve and disseminate knowledge of rehabilitation treatment. This legislation promoted the professionalization of VR by establishing graduate-level training programs throughout the United States. However, this increasing professionalism led to the alienation of many people who became part of the disability rights movement of the 1970s and 1980s. The ratio of federal to state matching funds changed from 50-50 to \$3 for every \$2 of state funds. The legislators also authorized 30 million dollars to the States for rehabilitation purposes and expanded annual funding. Research demonstration grants allowed state rehabilitation agencies or nonprofit agencies to conduct projects directed specifically at VR (4). Now, disability arenas such as the psychological, social, and behavioral components of disabilities were studied in a systematic manner. Results were then applied in training programs, policy and rehabilitation service mandates (15).

The Vocational Rehabilitation Act Amendments of 1965 expanded the federal state funding ratio to 75% to 25% and addressed extended evaluation for individuals with severe disabilities to determine if VR services would be beneficial. The Amendments also extended eligibility to include "behavior disorders," which made it possible for those with substance abuse problems, public offenders, and those who were socially disadvantaged to obtain VR services. However, this provision was removed in the 1973 Rehabilitation Act due to financial as well as time constraints.

In 1961, legislation was introduced requesting that Vocational Rehabilitation Agencies provide IL services; however, it failed to pass. In 1972, a new bill (HR 8395) was written and passed to replace existing VR legislation by including comprehensive rehabilitation services and IL provisions. This legislation was vetoed by President Nixon, who believed that IL would dilute the resources of the VR program. The bill was resubmitted in 1973 and once again vetoed, as the President's advisors felt that the rehabilitation of people without vocational potential was too expensive. In 1973, a compromise was reached and the Rehabilitation Act was made into law. Although the IL provisions were eliminated, an emphasis was placed on the delivery of VR services to individuals with severe disabilities.

The Rehabilitation Act of 1973 was a powerful piece of legislation and had a major impact on VR programs. Additional important features of the Act were the creation of the Individualized Written Rehabilitation Plans (now called the Individualized Plan for Employment or IPE) and consumer grievance procedures. These two innovative measures emphasized for the first time the notion of consumer empowerment, with simultaneous changes in language from "client" to "consumer." Now, clients were seen as consumers, and this change acknowledged that the traditional "paternalistic" attitude of the service provider was a barrier to rehabilitation. Consumers became more assertive than in the past and were empowered to make autonomous decisions with the assistance of trained VR professionals. In this paradigm, people with disabilities work as a team with the rehabilitation counselor, occupational therapist, physical therapist, psychiatrist, and other medical professionals, signaling a change from the past, when they were expected to be compliant recipients of care (4,15,21,22).

Consumer advocacy was a powerful driving force on the tenets of the Rehabilitation Act of 1973. The act included a number of provisions to address discrimination and environmental barriers, as follows: (a) Section 501, mandating that the federal government itself practices nondiscrimination in its hiring practice; (b) Section 502, establishing the Architectural and Transportation Compliance Board to enforce accessibility standards for persons with disabilities; (c) Section 503, prohibiting discrimination in the hiring process based on disability status (which applied only to federal contract recipients or subcontractors); and (d) Section 504, in which participation from any federally sponsored program was prohibited for any qualified person with a disability. These programs included schools (elementary, secondary, postsecondary), hospitals, clinics, and welfare agencies. Accessibility of programs was

emphasized. This legislation mandated that employers or institutions receiving federal funds were required to make “reasonable accommodations” for otherwise qualified people with disabilities. For employers, this meant job restructuring, workplace modifications, provision of specialized training, or ongoing support (4).

In 1974, the Rehabilitation Act of 1973 was amended to include a broader definition of the term “handicapped individual.” The new definition emphasized limitations in major life activities rather than only vocational objectives. In 1978 (4,1,23), a number of amendments were made to the Rehabilitation Act of 1973, most importantly, Title VII entitled “Comprehensive Services for Independent Living.” Its purpose was to authorize grants to states to provide independently living services for individuals with disabilities without emphasizing the employment component. A vocational outcome was not necessary for these services. In addition, a bill of rights section was included for those with disabilities, and the National Council on Independent Living was established. This amendment made centers for IL partners with the traditional rehabilitation program. The Rehabilitation Act Amendments of 1986 authorized state VR agencies to provide supported employment services to individuals with severe disabilities who were not capable of competitive employment. Consequently, long-term placement in workshops was viewed as a less than favorable option. This Amendment also increased the use of rehabilitation engineering to assist with independence (4).

The Americans with Disabilities Act (ADA; PL 101-336), a hallmark civil rights legislation for persons with disabilities, was passed in 1990 (15). Its purposes were to end discrimination against people with disabilities and to promote both their social and economic integration (23). To be covered under the ADA, either a mental or physical impairment exists that must “substantially limit” one or more major life activities (e.g., walk, eat, self-care, work, etc.); or the individual has a record of the impairment (e.g., cancer in remission, substance abuse in remission, records of mental illness, educational record depicting learning disability); or is regarded as disabled (e.g., the employer does not hire an individual for a sales position due to a facial birthmark). Contagious diseases (HIV/AIDS) were included in the law, though not in work situations where they may pose a “direct threat” to others. Other conditions such as pedophilia, kleptomania, compulsive gambling, and transvestism were not protected by the ADA. Subsequent court decisions have determined that impairments that are mitigated by corrective measures (mitigating measures) are not covered under the ADA. For example, high blood pressure and diabetes do not substantially limit major life activities when medication regimes are followed. These court decisions have had the effect of creating ambiguity in how the ADA is interpreted, raising concerns that its original antidiscrimination protections are being gradually eroded (4). As a consequence, the ADA Amendments Act was signed into law in September, 2008. Taking effect in January, 2009, the ADA Amendments Act is designed to protect the original ADA of 1990. The Amendments Act retains the ADA’s

definition of disability and maintains that the definition of disability should be viewed and interpreted in a “broad” manner. It offers clarification regarding what the law considers to be major life activities as well as mitigating measures. For example, it expands major life activities to include those that had not been specifically identified in the previous legislation, such as reading, bending, and communicating, and adds major bodily functions, such as the immune system and neurological functions. Under the Amendments Act, mitigating measures, not including contacts or eyeglasses, will not be taken into account when determining disability status. An impairment that is either in remission or episodic is considered a disability if a major life activity would be substantially limited when the impairment is in an active state. In addition, one “regarded as” having a disability is not entitled to a reasonable accommodation (24).

The ADA prohibits discrimination against people with disabilities in employment (Title I), public services (Title II), public transportation (Title III), places of public accommodation (Title IV), and telecommunications (Title V). The primary purpose of Title I is to provide equal employment opportunities to qualified individuals with disabilities. Under Title I, the ADA prohibits discrimination because of disability in the hiring, promotion, job training, and firing process (15). A qualified individual with disabilities is one who can perform the essential functions (e.g., word processing skills for a newspaper writer) of a job with or without a reasonable accommodation (e.g., voice-recognition computer software). Businesses with more than 15 employees are required to make reasonable accommodations for qualified candidates with disabilities unless such accommodations would impose “undue hardship.” Such accommodations might include improving worksite accessibility, equipment modification, work schedule modification, or provision of interpreters. Undue hardship is determined by the organization’s financial profile. Title II of the ADA prohibits discrimination against people with disabilities in state and local government programs such as the library, courtrooms, county museum, and public transportation must be accessible. Individuals with disabilities should have equal access to these services, and reasonable accommodations must be provided for these services (4).

Title III of the ADA, the public services provision, prohibits discrimination against persons with disabilities when using public establishments such as theatres, hotels, auditoriums, museums, and private schools. Both barrier removal and reasonable accommodations that are readily achievable (in terms of financial impact) are required. Title III underscores the fundamental right of Americans to enjoy all public accommodations in society (4). The presence of a disability should not preclude one from this freedom. Imagine not being able to use a hotel during a family vacation because there is no ramp to the front door. Title IV is the component of the ADA addressing telecommunication and requires that individuals with hearing and/or speech impediments have equal access to telephone services at a cost comparable to those without disabilities (15). Services include the Telecommunication Device

for the Deaf (a keyboard is used to communicate via telephone lines) or a Telephone Relay Service (in which a third-party operator relays messages from a nonspeaking patron to one who communicates through speech). Lastly, Title V prohibits retaliation or coercion toward individuals who use the ADA to protect their rights.

The Rehabilitation Act Amendments of 1992 emphasized consumer involvement in the policies and procedures of state VR agencies. These amendments emphasized employment outcomes for people with disabilities, commitment to IL services, informed choice, and consumer participation in VR process (4). In addition, Rehabilitation Advisory as well as Independent Living Councils were created and were required to be composed primarily of people with disabilities in order to provide guidance regarding agency policy and procedures. The order of selection process was also established for determining who would get services, with priority of services going to individuals whose disabilities were most severe. In addition, consumer autonomy was stressed. Each individualized rehabilitation plan must describe how the consumer was involved in plan development. Annual reviews of the plan are mandated, and the consumer or guardian must participate in the review and modifications to plans. Eligibility requirements were changed in that it was now assumed that the person could benefit from VR services and achieve an employment outcome, unless it could be shown otherwise (11). Terminology was changed; instead of “handicapped,” the term disabled was now used (15). Other amendment topics included support for transition from school-to-work, supported employment, on the job training, serving minorities, and personal care attendants.

In 1998, President Clinton signed the Workforce Investment Act (WIA; PL 105-220), which included the Rehabilitation Act Amendments (4,11,15). The WIA is based on a “one-stop” concept of locating job training, education and employment services available at a single location. The purpose of the one-stop career system was to address the “fragmentation” in service delivery that previously existed. Programs were streamlined and consolidated to avoid problems that occurred in the past with disjointed services. Now, all services are located in one arena (11). The one-stop shop provided a facility where an array of federally funded programs were available in one location. Programs include unemployment assistance resources, vocational training, placement counseling, vocational assessment, and daycare services for individuals while they utilized the one-stop services. This law emphasized increased consumer control of the vocational planning process. The Individualized Written Rehabilitation Plan was now called the IPE, and clients were expected to be active participants in plan development. Outreach to underserved minorities was also stressed. The law put more emphasis on the need for qualified VR counselors to provide services. A master’s degree in rehabilitation counseling and passing the certified rehabilitation counselor (CRC) examination were methods for establishing this qualified status (4).

In 1999, the Ticket to Work and Work Incentive Improvement Act (TWWIIA; PL 106-170) was passed, providing Supplemental Security Income (SSI) and Social Security

Disability Insurance (SSDI) beneficiaries with a “ticket” they may use to obtain VR services from an employment network of their choice. This program is voluntary and consumers may choose their own rehabilitation service vendor, designated as an Employer Network, or EN. Vendors can be either private or public entities. For example, ILCs, state VR agencies, educational institutions, and employment agencies are examples of potential employment networks. The TWWIIA also provided for the removal of work disincentives such as medical coverage. Starting in October 2000, Medicare and Medicaid coverage was expanded to more people with disabilities who were employed. With SSDI, a 9-month work trial (with a 3-month grace period) is allowed, so the person’s benefits are not affected for 12 months. Extended medical coverage through Medicare is provided for up to 93 months following the trial work period for those who are working. Consequently, employment rates can increase if individuals with disabilities do not believe they will lose benefits due to employment. These supplemental medical as well as Social Security benefits help remove important disincentives to employment for individuals with disabilities (4).

On February 1, 2001 President Bush announced the New Freedom Initiative as part of a nationwide effort to remove barriers in community living for people with disabilities. The initiative’s goals are to: (a) increase access through technology; (b) expand educational opportunities for youths with disabilities; (c) promote home ownership; (d) integrate Americans with disabilities into the workforce; (e) expand transportation options for persons with disabilities; and (f) promote full access to community life. Thus, this comprehensive plan’s mission is to ensure that every American has the opportunity to learn and develop skills, engage in meaningful work, have autonomy in daily activities, and participate in community life. The president emphasized that individuals with disabilities, families, caregivers, and advocates were involved in a listening session with the purpose of improving community integration (25).

## THE CONSUMER MOVEMENT IN REHABILITATION

As the consumer (instead of patient/client) movement grew in the late 1960s to early 1970s, with its emphasis on advocacy and self-determination, the time was ready for the IL and Disability Rights movements. The driving force of IL was that individuals with severe disabilities were able to both direct and manage their lives. Furthermore, the services and supports that people with disabilities need are best delivered by individuals who themselves have disabilities and whose knowledge about both disability and services is derived from firsthand experience. Empathy is a cornerstone of this model, with consumers serving and providing mentoring to other consumers. In this model, an individual with a disability may address the many concerns that a person with a newly acquired disability may encounter. Consumers may discuss adjustment to disability issues, adaptive equipment, and techniques for navigating

the many service systems (4). The model follows that of organizations such as Alcoholics Anonymous, in which substance use disorders are best addressed by those who have gone through a similar path.

### Empowerment of Consumers

Disability legislation continues to emphasize the fundamental right of individuals with disabilities to make decisions about their own lives (4). Since 1973, rehabilitation practice and legislation have been driven by consumer-counselor partnerships and consumer empowerment, which have been the underpinning of all rehabilitation legislation, as exemplified by the following:

- The 1978 Rehabilitation Act Amendments provided that individuals with disabilities be guaranteed more involvement in their rehabilitation plan;
- The 1986 Rehabilitation Act Amendments included support for individual consumer rights and revised the IPE format to include consumers' statements of their own rehabilitation goals;
- The 1990 ADA further strengthened consumer self-determination by ensuring rights in the areas of employment, transportation, public services, and public accommodations;
- The 1992 Amendments to the Rehabilitation Act also supported the movement toward self-determination.

Consumer empowerment is the driving force behind our current rehabilitation policy and practice paradigm. Since its inception, the IL movement has viewed consumer control as a necessary component of rehabilitation and direction, not only of the services needed by its individual constituents but also of the institutions and organizations that house its activities and administer its resources (4,15). Thus, the 1992 Amendments to the Rehabilitation Act required that a majority of ILC staff, management, and directors must be individuals with disabilities. This empowerment perspective sees the consumer as a competent change agent capable of identifying problems, finding solutions, and making independent decisions. Within this paradigm, the rehabilitation counselor serves as a guide or facilitator to problem solving and decision making. Knowledge is viewed as power, and the counselor encourages the consumer to gather information to enhance knowledge. The rehabilitation counselor practices informed consent and continually drives the point that the consumer is a competent agent in charge of his or her change (15).

### Consumerism, Accessibility, and Assistive Technology

Social, environmental, and cultural barriers have long kept people with disabilities from having full access to work, education, and participation in their communities. Technological advances have been recognized as a means of expanding opportunities for people with disabilities, helping them to surmount environmental barriers, enhance functional capacities, and maximize independence (26,27). Use of appropriate technology can improve the mobility, communication, and IL

skills of people with disabilities, thus dramatically enhancing their ability to become full participants in American society. To this end, the Technology-Related Assistance for Individuals with Disabilities Act was passed in 1988 to promote the use of technology services for people with disabilities (26). The Tech Act officially defined AT as "any item, piece of equipment or product system, whether acquired commercially off the shelf, modified or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities" (26). AT can range from "low-tech" devices such as walkers or canes to "high-tech" devices such as speech synthesizers or stair-climbing wheelchairs. This law was replaced by the Assistive Technology Act of 1998 (often called the "Tech Act"), which advocated statewide coordination and utilization of AT services and development of consumer-responsive technology programs (4). The 2004 amendments to the Tech Act promoted improved AT services through a standardized, statewide implementation process, which included plans for providing AT training to rehabilitation counselors (28).

Other laws affecting the lives of individuals with disabilities have also included technology as an essential component. For example, the Telecommunications Act of 1996 (PL 104-104) addressed the civil rights of people with disabilities by mandating that telecommunications services and equipment be "designed, developed, and fabricated to be accessible to and usable by individuals with disabilities, if readily achievable" (29,30). AT helps fulfill the legislative mandate of the Rehabilitation Act of 1973 and its subsequent 1986 and 1992 Amendments, which reinforce the need for active consumer participation in the VR process and emphasize consumer choice, self-determination, and consumer empowerment (31). Consistent with the emphasis on consumer involvement, the 1998 Amendments to the Rehabilitation Act mandate consideration of AT in provision of VR services (32). The importance of AT has also been increasingly recognized in provision of special education services to children with disabilities, as evidenced by the 1986 and 1990 amendments to the Individuals with Disabilities Education Act (IDEA), which mandated the inclusion of AT devices and services in education, and the 1997 Amendments to IDEA strengthened the role of AT in special education by requiring that AT services be considered for students who have an Individualized Education Program (IEP) (33). The ADA expanded public awareness of physical barriers and established requirements for uniform, national accessibility standards. Consistent with the mandate of the ADA, the Architectural and Transportation Barriers Compliance Board issued guidelines for accessible design in 1991, which were modified and adopted by the U.S. Department of Justice and became enforceable ADA Standards for Accessible Design (34).

While AT has significantly expanded job opportunities and improved the quality of life for many individuals with disabilities, the focus of AT services remains primarily on the individual, who must select and learn to use the assistive device. In contrast, the concept of "universal design" refers to

the design of products to be useable by all people, as much as possible, without the need for individual adaptation or specialized design. An example of universal design are pens and pencils with large rubber grips to minimize hand and wrist discomfort, products which are readily available in stores. Universal design and AT can be thought of as existing along a continuum, with universal design allowing access into the mainstream and AT meeting specific needs of the individual, with some overlap in products that can be either universal in design or AT (35).

AT's impact on the lives of people with disabilities is not limited to technology itself; it has also empowered consumers by enabling them to become full participants in selecting and making decisions about AT services and devices. AT has also made a significant contribution to current VR philosophy, helping to expand its view from normalization (where the person with a disability must adapt to becoming as "nondisabled" as possible) to an empowerment model, where individuals make their own decisions and enjoy full integration within the communities where they live and work (27).

## VR SERVICE SYSTEMS

Both VR and IL services foster consumer-driven services and are provided by systems of agencies and organizations that are often connected by common goals and principles, as well as funding mechanisms. The section below describes these systems in greater detail.

### VR Systems

The state-federal VR program has been a major provider of VR services since the enactment of federal legislation almost 90 years ago. Private, for-profit rehabilitation firms also provide VR services, as do private, nonprofit community-based rehabilitation programs. Another important VR provider is the Veterans Administration, which offers VR services to veterans with service-connected disabilities (36). Increasingly, ILCs are providing VR services, many in coordination with state VR agencies (5).

### Rehabilitation Counselors

Although many ILCs require that those providing services have firsthand experience with disability, rehabilitation counselors hired by state agencies or private rehabilitation firms are formally trained to provide counseling to people with disabilities. The rehabilitation counselor usually has a master's degree in rehabilitation counseling, although graduate degrees in guidance and counseling, or social work, are also common. However, rehabilitation counseling is unique among other counseling professions and is a specialization within the rehabilitation field (37). A rehabilitation counselor may be certified through the Commission on Rehabilitation Counselor Certification (CRCC) or licensed through his or her state. Although licensure or certification is not a standard requirement, state agencies may require it. The CRCC has defined the

scope of practice for rehabilitation counseling as being a process that helps individuals with diverse disabilities "to achieve their personal, career, and IL goals in the most integrated setting possible through the application of the counseling process" (37). The rehabilitation counselor may employ a broad range of strategies in this process, including assessment; diagnosis and treatment planning; career counseling; individual and/or group counseling, with an emphasis on helping individuals adjust to the impact of disability; coordination of services; methods to eliminate environmental and/or attitudinal barriers; job analysis, job development, and placement services; and assistance with job accommodations.

### State Vocational Rehabilitation Agencies

State VR agencies operate under federal legislation, the Rehabilitation Act Amendments, and are available in every state to individuals with disabilities. State agencies work with multiple community partners to provide outreach to individuals, as well as to implement services. These partners can include school systems, ILCs, community mental health agencies, hospitals and health care clinics, substance abuse centers, local support groups, other state and county employment programs, and a host of social service agencies (5). State VR agencies may also contract with private rehabilitation firms or with community-based rehabilitation programs for an array of services, including vocational evaluation, job placement services, supported employment, and/or job coaching.

In the state VR agency, rehabilitation counselors and consumers work together in partnership to develop a rehabilitation plan, the IPE. Mandated by the Rehabilitation Act of 1973, the IPE includes (a) a specific vocational goal and timelines for its achievement; (b) services necessary to achieve the goal; (c) secondary goals needed for goal achievement; (d) services and providers required for the secondary goals; (e) criteria and procedures for evaluating progress; (f) counselor and consumer responsibilities; and (g) an annual review for as long as the case is open (4,5). Objectives in the plan might include provision of a service such as treatment, training (e.g., college, on-the-job training), job placement, and specialized adaptive equipment or transportation.

### Private Rehabilitation

Private rehabilitation generally refers to services provided by rehabilitation practitioners employed by private firms that bill a third-party payer for their services (38). In the late 1970s and 1980s, there was a tremendous growth in the number of private, for-profit rehabilitation firms, largely due to state Workers Compensation legislation designed to foster rehabilitation of injured workers (39). As a consequence of this legislation, private rehabilitation firms emerged to meet the needs of insurance carriers and employers, who needed timely and efficient services (40,41). In addition, insurance companies were becoming increasingly concerned with controlling growing health care costs; they discovered that referring insured or ill workers early in the rehabilitation process could reduce their disability payments. Private rehabilitation firms tend to be

more efficient in their approach to helping individuals return to work than their state VR counterparts. Rehabilitation counselors in the private sector have smaller caseloads than counselors in state VR agencies, and they focus primarily on vocational guidance and placement. Counselors working in the private sector require basic business skills, knowledge of the insurance industry, an understanding of the worker's compensation system, expertise in legal and medical case management, and the ability to provide vocational expert testimony (42). Many rehabilitation counselors in the private sector are self-employed or co-owners of small firms (43), although there has been a trend in recent years for smaller firms to merge with larger managed care organizations, insurance companies, and other health care entities. Private rehabilitation counselors often contract with insurance carriers to provide VR services to individuals who qualify for these services through workers compensation, auto no-fault or long-term disability policies, and their services are provided within the insurers' parameters. Consequently, private rehabilitation firms are usually very responsive to the payer's goals and objectives. Because worker's compensation laws are governed by each state, rather than federal law, provision of VR services will vary among different states (5).

### VR Services

Although services vary according to individual needs, the VR process consists primarily of four stages, which generally occur in sequence: (a) evaluation, (b) planning, (c) treatment (provision of services), and (d) termination, or achievement of the vocational goal, usually placement in a job. The rehabilitation counselor generally begins the evaluation phase by means of an initial interview with the consumer to obtain information, as well as to provide information to assist the consumer in making an informed choice. During the evaluation phase, additional information may be needed prior to rehabilitation planning and obtained through medical evaluation, psychological evaluation, vocational assessment, or related diagnostic services (4). Cultivating relationships with local employers to promote employment of people with disabilities also is an important component of the VR process. The following are services commonly offered by VR agencies during the VR process.

### Vocational Assessment

VR begins with assessment of the consumer's vocational interests, abilities, and vocational potential. By providing information about an individual's strengths and weaknesses and identifying needed services, the vocational assessment helps the consumer and VR counselor set goals and establish a rehabilitation plan. Assessment may also be used to determine the consumer's potential to benefit from VR. Vocational assessment can help the counselor and consumer answer the following questions: (a) can you return to your former occupation? (b) would you be able to return to your previous occupation with job accommodations and AT? (c) which of your skills may be transferable to another occupation? and (d) what training or other services would help you become successfully employed?

Assessment is a multidisciplinary process that initially involves gathering data from a variety of sources, such as work and educational history, as well as medical records. For individuals who have received physical rehabilitation services, these records may include a medical examination and reports from the rehabilitation team, such as occupational and physical therapy. The VR counselor may also refer the consumer for additional assessment services, such as a psychological evaluation or a vocational evaluation. The psychological evaluation can provide helpful information regarding the individual's learning abilities, coping skills, and personality characteristics, while the vocational evaluation describes important work-related behaviors, capabilities, and interests.

Although the terms vocational evaluation and vocational assessment are often used interchangeably, vocational assessment is a general term that includes many different forms of evaluation. Vocational evaluation is defined specifically as a comprehensive assessment that utilizes a variety of tools, including paper-and-pencil tests, structured and unstructured interviews, and real or simulated work (44). With its focus on work-related abilities, a vocational evaluation may use work samples, situational assessments, and on-the-job evaluations. The work sample approach to measurement has been used most often in vocational evaluation, often through commercial work sample systems (e.g., VALPAR) designed to simulate specific jobs or a cluster of jobs; a vocational evaluation may also incorporate actual work samples from industry.

Using a variety of evaluation procedures can help verify other assessment data and thereby contribute to more accurate findings and recommendations (44). Cross-validating assessment data may be especially important for persons with disabilities, as concerns have been raised about the validity of paper-and-pencil tests for this population, particularly for individuals with severe disabilities (45). In addition, vocational evaluation may incorporate AT during the assessment process, for example, by modifying work samples or other test instruments, and by making recommendations that include consideration of specific AT devices that would maximize the consumer's vocational potential (46). For example, the vocational evaluator may recommend speech recognition software to enable a consumer with limited hand function to perform a job requiring computer access.

Evaluation of an individual's functional skills is an important part of the assessment process and can be applied to various domains, such as IL skills, interpersonal communication, sensory awareness, emotional stability, learning ability, and stamina. Many functional skills can be observed as part of a situational assessment or on-the-job evaluation, as well as through more formal methods, such as work samples and inventories. Sophisticated systems designed to measure a wide range of physical capacities such as lifting strength are also available, including the ERGOS Work Simulator and the BTE Simulator (47,48). These systems are more likely to be used as part of a Functional Capacities Evaluation (FCE) conducted in a work conditioning program, hospital, or clinic, rather than during a vocational evaluation.

## Job Placement

Job placement includes an array of services, such as job-seeking skills training, direct placement, job accommodation, supported employment, and job development. These services may be offered by rehabilitation counselors or by placement professionals (often called placement specialists or employment specialists). Job analysis is sometimes provided as a service in conjunction with job placement, though it may also occur as part of a vocational assessment. Employment readiness is an important consideration and may be affected by psychosocial factors, availability of accessible transportation, and medical status, including stability of the medical condition and capacities for stamina and endurance. Psychological readiness to work, including motivation, self-esteem, and coping resources also must be addressed.

Once the individual is ready to seek employment, he or she must develop or refine the employment skills that will be required for success in the job search, which will largely be determined by past experience. For example, the individual who acquired a disability later in life and who has a long work history will likely need to refine job-seeking skills that include addressing disability issues with potential employers. The individual with virtually no work history will require far more extensive job seeking skills training, which typically includes identifying and following up on job leads, resume writing, application completion, and interviewing skills (5).

Job placement activities can be viewed along a continuum, ranging from self-placement (usually called client-centered placement) to the counselor assuming all placement responsibility, often referred to as selective placement (49). The skills and personality traits of the job seeker, the nature of the disability, local labor market conditions and opportunities, and even luck influence the extent of counselor involvement that may be needed. The rehabilitation plan will target the consumer's job goal, specify acceptable geographic and environmental criteria, consider the types of job accommodations needed, and specify follow-up and support services required. A primary role of the VR counselor or placement professional is to assist the consumer in developing job seeking skills, using such tools as coaching and role playing or videotaping a mock job interview. In addition to job seeking skills, he or she must also know how to respond to questions about disability, either on an application or in an interview. Knowledge of legal protections, such as those stipulated by the ADA, is critical for the individual with a disability who is seeking employment (5).

Consumers may also need help with identifying and learning how to request job accommodations. Although the individual must learn what types of accommodations are required, the VR counselor or placement specialist can often act as a consultant to the employer and help negotiate the accommodation process. As stipulated by the ADA, the employer is required to make reasonable accommodations, but this term is subject to various definitions. Some employers view job accommodations as prohibitively expensive, although the majority of accommodations cost less than \$500 (50). In fact, job accommodations can reduce worker's compensation

and other costs. Some accommodations may be as simple as a rearrangement of equipment. For example, for individuals using wheelchairs, a height adjustable desk, a voice activated speakerphone, or moving office supplies to accessible drawers are low cost and simple accommodations. Other examples of accommodations include job restructuring (e.g., trading off job tasks with other workers), flexible schedules, large print, allowing use of personal care attendants or service animals, and large-button phones.

Supported employment is another model of job placement that is particularly effective for individuals with severe disabilities, such as TBI, developmental disabilities, or significant cognitive limitations. In contrast to the traditional model of job placement, which assumes that the individual is job-ready and has been sufficiently trained before obtaining a job, supported employment uses a "place-train" approach. That is, the individual is placed in a regular, competitive job setting and given needed support, such as assistance from a job coach and/or work mentor, to provide training on the job and ensure success (51).

Once the consumer obtains employment, follow-up services with both consumer and employer help to ensure a successful outcome and are an important step in the job placement process. The rehabilitation counselor or placement professional may need to intervene either with the consumer, employer, or both, to solve problems as they occur. Further job accommodations may be needed to help resolve difficulties with performance. However, if the consumer is ultimately unable to perform the job, the consumer and counselor may agree that it would be best to discontinue the job, as VR involves a successful outcome for both the consumer and the employer. Placement professionals must establish positive relationships with employers, and ultimate employment success may require provision of long-term follow-up services (52).

Job development is also an important component of job placement services. People with disabilities continue to encounter discrimination from employers, who may object to hiring individuals with disabilities due to common employer "myths" about individuals with disabilities, such as a belief that they will increase their insurance rates, will be subject to accidents, or have problems with job performance or stability. Thus, rehabilitation counselors and placement professionals need to dispel these misconceptions and to actively promote the benefits to employers of hiring individuals with disabilities. Rehabilitation professionals must be visible and active in business organizations and build credibility within the community. Services that can be marketed include recruitment and referral of qualified applicants, consultant services (e.g., ADA compliance, job accommodation, and disability awareness training programs), employee assistance programming, and support and follow-up services (52). Many placement programs also develop business advisory boards constituted of employers and other important business contacts in their community to share ideas and develop strategies for improving employment opportunities for people with disabilities (53).

Job analysis can be critical to the ultimate success of job placement efforts. A thorough analysis of a particular job

in a certain environment can assist the VR professional in identifying appropriate job accommodations or determining if a job is feasible for the consumer. For example, when providing services to an injured worker, the rehabilitation counselor may conduct an analysis of the worker's previous job or of alternate jobs being considered and provide this information to the worker's treating physician, who can then determine if the job is consistent with the individual's physical capacities. The job must be analyzed for the skills, knowledge, and abilities needed, characteristics of the work environment, and specific job tasks (54). An analysis of environmental factors may consider parking at the worksite, restrooms, cafeteria, and building accessibility. The physical demands of the job must be assessed, such as lifting, grasping, standing, walking, sitting, talking, hearing, writing, and reading. For people with cognitive or affective limitations, other critical factors might include the work atmosphere (e.g., busy or relaxed) and cognitive demands (e.g., memory, reasoning, problem solving). Job analysis requires that the rehabilitation counselor possesses considerable expertise in a variety of areas, including knowledge of disabilities, job accommodations, employer needs, accessibility standards, business practices, and the roles of labor and management (42).

## EMPLOYMENT OUTCOMES: A REVIEW OF FINDINGS

An overview of rehabilitation studies on employment, VR, and IL outcomes among people with physical disabilities suggests a number of variables that may assist rehabilitation professionals in identifying those individuals who can best benefit from their services. This research can help rehabilitation professionals better understand both environmental and personal characteristics that promote or hinder employment outcomes for individuals with disabilities. Equipped with these research findings, professionals can design programs and/or implement specialized techniques and knowledge to help persons with disabilities be successful in the rehabilitation arena (4).

Several studies have reported certain demographic factors such as race, gender, and disability severity, and disability characteristics as factors related to vocational outcomes (55–58). In general, those with successful vocational outcomes tend to be Caucasian, young adults, well-educated, and had a successful career prior to the acquired disability (59–61). However, because consumer variables are easier to identify and measure than environmental variables, these research findings may at least partly reflect a lack of clear-cut strategies for assessing the impact of environmental factors on VR outcomes (62). As more research is conducted based on the conceptual model of the International Classification of Functioning, Disability, and Health (ICF) discussed earlier, environmental facilitators and barriers can be specifically assessed for their impact on rehabilitation outcomes.

Beveridge and Fabian (55) determined that when consumers' IPE is congruent with the employment outcome, they are more likely to earn higher wages. Although this finding

was applicable to all consumers, it was particularly evident for those with cognitive disabilities. In addition, individuals with physical disabilities earned substantially more than persons with sensory and mental disabilities.

Age at the time of disability, premorbid employment status, work status, and psychological distress were also found to be significant predictors of successful employment for a group of people with TBI. In fact, learning as well as psychological disabilities coupled with TBI tended to have a negative impact on employment outcomes for this population (57,63). Individuals who are injured either at a very young age or over age 40 are less likely to return to work (58,64).

Psychosocial factors also appear to play an important role in employment outcomes for individuals with disabilities. For example, consumers' self-awareness is a key factor in returning to employment (65). Poor self-awareness, as well as unrealistic goals, are primary reasons why consumers fail to secure employment following provision of VR services. Motivation appears to predict employment status among an array of disability groups (59–61). Internal locus of control is frequently discussed as an important predictor of job search and employment success. This proactive stance tends to produce more successful outcomes compared to consumers who perceive themselves as being more externally controlled (66,67).

In a landmark study of the outcomes and effectiveness of the state-federal VR system, the Longitudinal Study of the Vocational Rehabilitation Services Program (LSVRSP), used longitudinal design to track consumers' progress over a period of 3 years (68). Of those participants who received services, 69% obtained an employment outcome, which is defined as either competitive or noncompetitive employment over a continuous 90-day period. Of those consumers with an employment outcome, 75% obtained competitive employment, while 25% received noncompetitive placements, which included supported employment, extended employment, homemaker, and unpaid family worker. The study identified a number of consumer characteristics, including type of disability, which had a significant impact on achievement of an employment outcome. For example, consumers with a hearing or orthopedic impairment were more likely to attain an employment outcome. Other characteristics associated with an employment outcome were working at time of application, higher number of dependents, and higher self-esteem. In contrast, individuals receiving disability benefits (e.g., SSI, SSDI) were less likely to obtain employment. The LSVRSP also examined the relationship of VR services to employment outcome and found that provision of job placement, on-the-job training, and business/vocational training were significant predictors of employment. That is, consumers who had received these services were more likely to be employed at follow-up 3 years later.

## CONCLUSION

Historically, VR and IL services often seemed to have opposing goals, with the early developers of IL seeing VR professionals as

creating more barriers for individuals with disabilities through their paternalistic attitudes and origins in the medical model of disability. The consumer movement has been successful in effecting changes in policies, driving legislative mandates that have promoted consumer empowerment and facilitated the gradual merging of the goals of both VR and IL. Both VR and IL can be seen as serving essential and complementary roles in the rehabilitation process. VR and IL increasingly share a more holistic, ecological understanding of disability that stresses the role of the environment in either magnifying or minimizing the impact of impairment. In VR, focus has been shifting from efforts to change the person with the disability to removing or modifying barriers in the environment that hinder the person from being an active participant in work and society. These programs also complement each other in many ways. With their goal-oriented approach to services, VR programs assist consumers in obtaining employment or furthering their education to expand future career opportunities. IL programs foster greater sense of accomplishment and control over one's own destiny. While promoting self-direction and self-sufficiency, they expand life opportunities and social identity for individuals with disabilities. By promoting independence, IL facilitates vocational options and thus can be seen to work in tandem with VR services.

In the past, the roles of VR and IL professionals also differed significantly but now are becoming more similar. Both rehabilitation and IL specialists are change agents who act as facilitators to help people with disabilities maximize their independence, participate as fully as possible in their communities, and advocate for their own needs and interests. However, VR and IL differ in the types of outcomes that each program emphasizes. VR programs define a successful outcome as employment, and preferably paid, competitive employment. Such an outcome is measurable, and outcome data from VR services can be gathered and statistically analyzed to assess its overall performance. At the same time, using employment as the sole criteria for success provides a narrow view of rehabilitation (69). In contrast, a successful outcome in IL is more individualized and broadly defined, as it is based on each consumer's needs and desires, and usually pertains to progress in areas that are more difficult to pinpoint and measure, such as quality of life, coping skills, autonomy, and self-dignity. The ICF model offers a multidimensional perspective of health, in which persons with health conditions may or may not experience disability, depending on their interaction with the environment; this holds promise as a conceptual framework that could help unify VR and IL even further. For example, in the VR system, criteria based on the ICF could be used to measure indicators that reflect progress in other important aspects of life and more precisely assess program effectiveness, rather than relying solely on employment outcome (62). Such indicators could align closely with consumer goals of IL, such as improved quality of life. In addition, ICF-based criteria could include environmental factors that have long been recognized by the IL movement as being critical in the lives of individuals who experience or are likely to experience disability.

# Community Participation and the Environment: Theoretical, Assessment and Clinical Implications

## INTRODUCTION

Mrs. X and Mrs. Y are both 62 years old. One year ago, both had right middle cerebral artery infarctions with resultant left upper- and lower-extremity weakness and left-sided visual inattention. The hospital course for both included admission to an acute care hospital followed by a 3-week stay at an acute rehabilitation hospital. Both were discharged home with home services. Mrs. X and Mrs. Y have supportive spouses who live with them and have children who live nearby. Following their strokes, Mrs. X and Mrs. Y retired. Both are able to walk unlimited distances in the home and community settings with a standard cane, though both indicate they walk slower and shorter distances than before the stroke. Both have discontinued driving. Both have gross grip strength of the left upper extremity but are unable to perform fine motor activities. Active shoulder range of motion is about 30% in the left upper extremity.

Mrs. X lives in a two-story townhouse in a highly populated urban area. A post office, grocery store, two community parks, the church she regularly attends, and a bus stop are located within five blocks of her home. There are ample level well-maintained sidewalks that are wide and well lit. Benches are scattered throughout the sidewalks, buses service the area frequently, and public transportation services for persons with disabilities are available. Mrs. X's activities include visiting friends and family almost daily, volunteering to teach English classes at her church once a week, and participating in a book-of-the-month club that meets at her neighbor's house, which she has just joined. When the weather is nice, she takes walks in the nearby park. Mrs. X has stopped grocery shopping since having her stroke and instead uses an online service that delivers the groceries to her home. Mrs. X generally gets around her community several times a week either by walking or by getting a ride with her friends and seems to have a fairly high degree of participation in her complex daily activities.

By contrast, Mrs. Y lives in a single level home in a suburban community. The town center is 2 miles away and contains a post office, library, and town hall with parking several hundred feet from the main entrances. Most of these buildings have stairs at the front entrance and a ramped access further from

the stairs. There is a small grocery store a half mile from her home but they do not deliver groceries and a larger one 4 miles away. Before her stroke, she worked in the local school system and exercised at the local YMCA that was located 10 miles from her home. Most of her friends are scattered around town, particularly near the YMCA. The church Mrs. Y regularly attended prior to her stroke is 5 miles from her home.

Many of the sidewalks in Mrs. Y's communities are uneven and are poorly maintained. A public transportation service does exist; however, the bus only comes twice a day. Many of the buildings have ramp access that is difficult to get to, stairs that have one railing, and limited parking. Mrs. Y has significantly curtailed her social activities since having her stroke, but she is still able to take care of the inside of her home. This includes vacuuming, preparing hot meals, and shopping for estate jewelry on e-bay. Mrs. Y was considering volunteering at a local bookstore in town; however, coordinating with her husband's schedule proved to be too difficult. Mrs. Y is quite active in her home and often entertains friends and family in her home, but her community mobility is very limited and she has a rather low participation in her complex daily community activities (Fig. 18-1).

Despite the identical pathology, impairments, and functional limitations, the community participation levels of Mrs. X and Mrs. Y are very different. Mrs. X continued to participate in community activities; however, Mrs. Y did not. Medical providers are keenly aware of this paradox, but why does it exist? Is it even something that rehabilitation professionals should consider? If rehabilitation professionals should address this, how do we intervene to optimize community participation and the community-environment interaction? How do we assess the community-environment interaction?

This chapter reviews notions of how the environment impacts participation among adults with mobility limitations. We will discuss theoretical and conceptual frameworks linking the environment to participation, discuss methodological considerations regarding assessment of participation and the community environment, review the literature linking the community environment to participation among adults with mobility limitations, and, lastly, discuss several clinical

**FIGURE 18-1.** Depictions of Mrs. X (**A**) and Mrs. Y's (**B**) communities.

implications in this area of rehabilitation science. Our focus of this review is on the physical aspects of the environment. Elements of the social, political, attitudinal, or technological aspects of the environment are not reviewed in this chapter.

## THEORETICAL AND CONCEPTUAL CONSIDERATIONS

### Community Participation

*“Participation”* is a term used in the World Health Organization’s International Classification of Functioning, Disability, and Health (ICF) and is defined as “a person’s involvement in a

life situation (1).” The concept of “life situation” pertains to areas in which people attain and define roles such as seeking and maintaining employment, seeking and securing an education, managing a household, and being a care provider. Nine domains are listed in the ICF that pertain to the activities and participations of people: learning and applying knowledge; general tasks and demands; communication; mobility; self-care; domestic life; interpersonal interactions and relationships; major life areas; and community, social, and civic life (1). Thus, the domain of *participation* addresses the extent to which and how people engage in complex day-to-day activities that comprise their daily lives. Fougeyrollas et al. (2) describe a similar concept “life habits” and define life habits as “daily activities

and social roles that ensure the survival and development of a person in society throughout his or her life.”

The term “participation” is similar to the terms *handicap*, defined as “a disadvantage for an individual that limits or prevents the fulfillment of a role that is normal for that individual (3),” and *disability*, defined as “restrictions in personal and social role behaviors (4,5).” The concept that all these three terms are referring to encompasses the extent to which people engage in the *complex daily activities that comprise the roles and activities of their daily lives*. These broad role activities occur in the home and community setting. For the purposes of this chapter, however, we focus on community daily activities (community participation)—that is, activities that people do in their community when they leave their home—rather than on home activities.

Performance of complex daily activities is likely to be influenced by a multitude of factors. Managing one’s health, for example, entails scheduling an appointment during a time that is compatible for the patient, which is dependent upon the schedule and ability of the patient or his or her caregivers. A doctor’s visit entails securing transportation to the facility, which may entail public transportation, adaptive transportation, or the person driving himself or herself. Whether the patient takes public transportation or drives, he or she needs to navigate the physical premises of a parking garage and/or office building and arrive at the (correct) location of the appointment. Once at the correct location, the patient needs to navigate waiting rooms and small examining rooms, change clothing if necessary, may need to transfer onto equipment that is not adaptive, and pay for the service. Then, the patient needs to reverse all of these to get back to the origination point! “Going to the doctor’s office” thus comprises a number of activities including transferring, walking or propelling a wheelchair, driving or securing transportation, dressing, managing money or billing payment, and coordinating a calendar. These factors in turn are likely to be influenced by a person’s level of function, cognitive status, sensory systems and emotional status, the availability of social supports and other programs in the environment, and the presence of environmental obstacles or barriers that impede a patient’s ability to get to the doctor’s office.

The ICF model provides a conceptual framework to examine the complex processes that are involved in the above example. Conceptually, the model proposes that *participation* is influenced by an individual’s *body structure and function* (defined as anatomical parts and physiological functions of organs and body systems) and his or her *activity* levels (defined as the execution of a task or action by the individual) (1). Other disablement theoretical models suggest similar relationships among body structures (impairments), functional activity (limitation in function), and performance of role behaviors (disability) (4,5). Conceptual frameworks help clinicians and researchers organize the complicated array of factors that influence health and health problems.

The ICF, however, also functions as a structured classification system of health and disability outcomes. The ICF provides a detailed description of relevant items in body systems, functions, activities, and participation. Thus, items from assessment

**FIGURE 18-2.** International Classification of Functioning, Disability, and Health.

instruments can be “linked” to the respective ICF identifiers in respective domains. This type of classification system and linking strategy can be useful to clinicians and researchers. For clinicians, it can help guide the assessment of clinically relevant factors in various patient populations (including the selection of measurement instruments). For researchers, it can aid in understanding the conceptual underpinnings of instruments to guide selection of the best instrument for the factor of interest to study. Indeed, an extensive amount of research on developing and validating the ICF classification structure is currently underway, with rules for linking instruments to ICF classification categories developed and validated (6).

The example described previously in this section, however, does not *solely* entail elements of body systems, functions, activities, or participation. Rather, this scenario is likely to be influenced by factors outside the individual (e.g., the environment) as well as internal behavioral or motivational factors. Environmental and intra-individual behavioral and personal factors in the ICF framework are proposed to be contextual factors that modify the relationships among body systems, functions, activities, and participation (1) (Fig. 18-2). These factors represent the social and physical circumstances in which the person lives—that is, characteristics of the person (e.g., attitudes) or elements of the environment (1,7–14). The role of the environment in disablement is also emphasized in the Institute of Medicine’s 1997 report that states a person’s involvement in life activities results from the interaction of the person within the environment in which the person exists. Limitations occur when the environment does not fit the individual (12,13). Exactly how, however, would the environment impact participation among persons with functional limitations and disabilities? What are the important elements of the environment that need to be considered from a clinical perspective? To understand these questions, we need to understand the conceptual underpinnings of environmental assessment.

### Conceptual Notions of the Environment-Participation Interaction

The environment may be viewed as everything external to the individual and is believed to have an impact on people’s behaviors and health outcomes. Researchers in the fields of

transportation and public health have shown that housing density, land use diversity, and street connectivity and design are related to how people navigate their community (15–17). People who live in environments with greater residential to commercial mixes have higher physical activity levels compared to those persons who live in environments that are more residential (18,19–21). People who live closer to work establishments are more likely to walk to work, thereby having higher levels of physical activity (19). Generally, environments that are characterized as more “walkable” are associated with more physical activity patterns among their residents as compared to environments that are less “walkable” (20,22). Research linking environmental factors to transportation and physical activity sheds some interesting perspectives into environment-participation research. Will these “global” factors of land use mix and street connectivity have a role in determining participation levels of people with functional limitations and disabilities?

*Participation* in daily life activities is a much more complex phenomenon than engaging in physical activity or navigating one’s community. Which aspects of the environment impact participation? What are the characteristics of the environment-participation interaction? There are several conceptual frameworks in the field of rehabilitation that suggest answers to these questions. Fougereyrollas et al., in their early conceptual notions on how the environment was related to participation, defined “environment” as all facilitators and barriers external to the individual that influence participation (8). They suggested that the environment has different “levels” of influence: “micro personal,” “meso community,” and “macro societal” and identified four domains that were important for participation: (a) socioeconomic organization (e.g., family structure, political systems, and economic systems), (b) social roles (e.g., law, values, and attitudes), (c) nature (e.g., geography, climate, and time), and (d) development (e.g., architecture, land development, and technology) (8,23).

In the ICF, the “environment” is identified as a *contextual* factor that has positive and negative attributes that could either enhance or restrict one’s level of involvement in life activities—that is, the environment is the “background” in which people’s life situations are embedded. The ICF organizes environmental factors into two levels: (a) individual and (b) societal. The individual level pertains to the immediate environment of the individual including settings such as home, workplace, and school. Physical and material features of the environment as well as direct contacts with people in the environment are included in this level. The societal level includes the formal and informal social structures, services, and overarching approaches or systems in the community or society that have an impact on individuals. Organizations and services related to work environment, community activities, government agencies, communication and transportation services, and informal social networks as well as laws, regulations, formal and informal rules, attitudes, and ideologies are included in this level. The ICF organizes environmental factors into five domains: (a) products and technology; (b) natural environment and human-made changes; (c) support and

**FIGURE 18-3.** Depiction of environment as a contextual factor in the International Classification of Functioning, Disability, and Health.

relationships; (d) attitudes; and (e) services, systems, and policies (1) (Fig. 18-3; Table 18-1).

Assessment of each of the ICF environmental domains is evolving. While some researchers have developed approaches to assess the broad array of environmental factors (24), others have elaborated on physical aspects of the environment. Shumway-Cook et al. (25) developed a community environment assessment that identifies eight dimensions of the physical environmental domain: (a) temporal, (b) physical load, (c) terrain, (d) postural transitions, (e) distance, (f) density, (g) attentional demands, and (h) ambient conditions. Others ascertain the presence of community mobility barriers, mobility devices and technologies, and transportation facilitators (26).

It is not entirely clear which elements of the environment are relevant for rehabilitation considerations. It is clear, though, that the environment in which people live is complex and entails a number of factors that have elements that could impact the degree to which people with mobility limitations could be involved in their life activities, and it is likely these factors range from the factors that individuals directly interact with to societal and cultural factors.

### Measurement Considerations

There are several methodological challenges to conducting and interpreting research on the links between the environment and participation. First, measurement of participation and environment is paramount to assessing the relationships between these complex phenomena. Researchers need valid and reliable measures of participation and the environment—with the assessments for each conducted in a manner that minimizes bias in the statistical relationships. The complexity of this, however, is substantial. Both participation and environment are complex domains, and assessing participation in terms of the environment in which people live is a complicated phenomenon.

**TABLE 18.1** Description of Environmental Domains in the International Classification of Functioning, Disability, and Health<sup>a</sup>

Domain	Description
Products and technology	The natural or human-made products or systems of products, equipment, and technology in an individual's immediate environment, that are gathered created, produced, or manufactured
Natural environment and human-made changes to environment	Animate and inanimate elements of the natural or physical environment, and components of that environment that have been modified by people as well as characteristics of the population in that environment
Supports and relationships	People or animals that provide practical physical or emotional support, nurturing, protection and assistance, and relationship with other persons in the home, place of work, school or at play or in other aspects of their daily lives
Attitudes	The attitudes that are the observable consequences of customs, practices, ideologies, values, norms, factual beliefs, and religious beliefs. The attitudes classified are those of people external to the person whose situation is being described, not of the person himself or herself.
Services, systems, and policies	Services comprise structured programs, operations, and services, public, private, or voluntary, established at a local, community, regional, national, or international level by employers, associations, organizations, agencies, or government in order to meet the needs of individuals and include the persons who provide these services. Systems and policies respectively comprise the administrative control and monitoring mechanisms, rules, regulations, and standards established by local, regional, national and international government, or other recognized authorities, which organize services, programs, and other infrastructural activities in various sectors of society.

## Participation

While there are numerous instruments available that assess activity (or function), there are fewer assessments of participation. Since the formulation of the ICF, however, several new instruments have been published that assess participation. One critical element of participation assessment is that the domains tapped should reflect the complex daily activities or life situations of people. Furthermore, if the aim of the instrument is to assess participation as a separate component of activity, then items pertaining to activity or function should not be included in the scale. Many measures in rehabilitation have items pertaining to activity and participation levels, which makes interpretation of the literature difficult. Below we describe a few published surveys assessing participation. Although we believe the conceptual and psychometric properties of these measures are good, there are a number of other valid and conceptually sound instruments ascertaining participation that could be used.

The Craig Handicap Assessment and Reporting Technique (CHART) is a 32-item self-report instrument ascertaining level of participation across six domains: (a) physical independence, (b) cognitive independence, (c) mobility, (d) occupation, (e) social integration, and (f) economic self-sufficiency. Each domain is scored on a 0 to 100 scale with higher scores indicating more participation. A score of 100 represents the participation level of persons without disabilities. A short 20-item version of the CHART is also available (CHART-20). Reliability and validity for the CHART and the CHART-20 are published (27).

The Late-Life Disability Instrument (LLDI) assesses two dimensions of participation: frequency and limitation (28). The frequency dimension pertains to the degree to which people participate in various complex daily life activities; the

limitation dimension pertains to the degree to which people perceive they are limited in performing complex daily activities. The instrument includes 16 items for both the frequency and limitation scales and was developed for use in a general aging population. Thus there are a total of 32 items in the instrument, but the same items are assessed in terms of frequency and limitation—an important and unique distinction of this scale in comparison to other instruments. Factor analyses of the instrument identified two subscales in each domain. The frequency domain includes social and management subscales and the limitation domain includes instrumental and personal subscales. Reliability and validity of the LLDI are adequate (28).

The Assessment of Life Habits (LIFE-H 3.0) is another instrument that is designed to assess participation on a general population of people with disabilities (2,29). The LIFE-H 3.0 scale is a 69-item survey that ascertains degree of difficulty in carrying out daily activities and social roles and the type of assistance needed to carry out the habits in 12 categories: nutrition, fitness, personal care, communication, housing, mobility, responsibilities, interpersonal relationships, community life, education, employment, and recreation. The instrument can be scored in subdomains or overall summary scores. Validity and reliability are acceptable (30,31).

Gray et al. developed the participation survey/mobility (PARTS/M) to ascertain participation levels in the domains of activity and participation proposed in the ICF (32). The instrument assesses participation in 20 life activities that address six domains: self-care; mobility; domestic life; interpersonal interactions and relationships; major life areas; and community, social, and civic life. Temporal, health-related limitations, evaluative, and environmental support are assessed. Validity and reliability are adequate (32).

**TABLE 18.2** Environment Measurement Approaches

Approach	Description	Strengths	Weaknesses
Neighborhood land use, density, and connectivity	GIS and GPS technologies used to identify land use mix, density, and connectivity	Observational measurement method (not biased by self-report), technologies readily available	Does not capture barriers and facilitators at the street level, which may be important for participation Focus is on physical environment and neighborhood transportation characteristics. Broad view of environment as per the ICF is limited
Observed barriers and facilitators	Interviewer assessment of presence of barriers of a particular house or neighborhood	Observational measurement method (not biased by self-report), reliable	Time-consuming, not feasible for large epidemiological study
Self-reported environment (perceived impact); barriers encountered or avoided; characterize environment			
Self-reported environment: perceived impact	Self-report assessment of the degree to which the environment impacts participation, includes accessibility	Seems to be reliable	May create a statistical bias: artificially correlated with disability (participation). Barriers or facilitators perceived may not be actual elements of the individual's environment.
Self-reported environment: barriers encountered or avoided	Self-report assessment of the extent to which barriers are avoided	Reliable	Observational method time-consuming and not feasible for large epidemiological studies. Assessment is confounded by functional ability.
Self-reported environment: characterize the environment	Self-report or observational assessment of actual elements of the environment	Representation of the environment irrespective of level of function or disability	Some domains or aspects of the environment may be difficult to reliably self-report. Observational methods are time-consuming and not feasible for use in large epidemiological studies.

The physical role, social role, and emotional role subscales of the SF-36 (33,34) are sometimes used as indicators of participation; however, these subscales do not fully capture the notion of participation as defined by the ICF. There are also a number of instruments that ascertain the degree of difficulty or the amount of help needed to perform instrumental activities of daily living (IADL) and activities of daily living (ADL). Though historically IADL and ADL assessments have been considered disability (or participation) level assessments, these instruments ascertain a fairly advanced stage of disability or participation restriction. As such, they have ceiling effects and are not usually very sensitive to change. These assessment instruments have, however, been used in a number of national surveys and comparison to normative populations is useful.

### Environment

There are three general approaches to ascertain elements of the environment: (a) objective assessment of density and structure using technology and land use data, (b) observational

assessments, and (c) self-report approaches that inquire about the impact the environment has on one's level of participation or characterizes the physical, political, and social aspects of the environment (Table 18-2). As mentioned previously, the environment is, viewed broadly, consisting of social, political, technological, and attitudinal elements. While there is an extensive scientific literature on the wide array of environmental factors and participation outcomes, we focus this review of instruments and the literature primarily on physical elements of the environment and their relation to participation level outcomes.

### Global Positioning Systems and Environment Layout

Global positioning systems (GPSs) allow objective assessment of the structural layout of communities and neighborhoods including the transportation infrastructure consisting of roads and crosswalks, the location of buildings and houses, and even direct mapping at the street level. The GPS is a technology

that can provide a relatively precise geographic location across the earth. GPS comprises of a number of satellites that orbit the earth and simultaneously emit their satellite location in a signal. Geographic locations on the earth can be calculated from GPS receivers using triangulation from at least four GPS satellite signals (35). GPS technology became operational in 1995, and since then, an increasing number of GPS-enabled products have become available for consumer use, such as cars, phones, and watches. Geographic information systems (GISs) (36) data represent real-world objects such as roads, buildings, and parks with digitized coordinates from GPSs. GIS incorporates different types of data, such as satellite images, elevation change, and street maps, into an integrated database organized around points on the earth allowing multiple attributes of any given geographic point to be queried. The presence of parks, walking trails, gyms, and other environmental factors that facilitate walking can be identified and counted from GIS data. The relative number of these facilitators within a 1-mile radius to a person's home can then be used to create a walkability index (37,38).

GPS and GIS technologies have corresponded with the development of new web-based interface systems that have created user-friendly and cost-free methods to query map data even at the street level. The extent of these resources varies between different regions of the globe. Many of the United States' major urban areas have detailed GPS and GIS mapping data at the street level, with GPS technology available throughout most of the United States. It is not, however, clear whether and how these sources can be used clinically or in clinical research to identify environment factors.

### Observational

Shumway-Cook et al. (25) developed an observational approach in which specific factors of the environment comprising the physical domain are assessed by observing people navigate their environment and participate in complex daily activities. The administration of the measure involves a structured observational encounter between a researcher and a participant—that is, a researcher observes and videotapes community mobility activities such as going to a grocery store or seeing a health care provider. Though this approach provides the investigator with an independent assessment of environmental factors, the limitations are the protocol's cost and the time it takes to administer it. While having good objective observational assessment elements, the Shumway-Cook protocol is not feasible in large-scale field studies where feasibility, study costs, and participant burden are paramount.

### Self-Report Assessment

A feasible approach for large cohort field studies is the use of self-report assessment techniques, and there are several published instruments using this measurement technique. The CHIEF is a 24-item self-report instrument that assesses the frequency at which people encounter environmental barriers related to attitudes and support, services and assistance, physical and architectural, policies, and work and school, and the

person's perceived impact of each environmental factor on his or her daily life (24). Respondents are asked to indicate how often various barriers in the environment have been a problem over the past 12 months. If environmental factors have been a problem, persons are asked to indicate whether the factor has been a big or little problem. Reliability and validity for all domains are acceptable (24). The Measure of the Quality of Environment is a 72-item self-report instrument that assesses the extent to which various barriers and facilitators of the environment influence people's participation in daily life activities (39). Instruments such as those reviewed above are important for identifying relevant environmental domains as well as important barriers and facilitators. However, measuring the impact the environment has on participation in a manner that assesses the environment and participation elements at the same time could produce a biased association with participation outcomes. For example, if people indicated that their environment contained a high number of elements that impacted their participation in life activities, the association between this measure and a measure of participation outcome could be statistically inflated. To examine how environmental factors affect people's involvement in daily activities, a better approach may be to have people characterize the extent to which a person's environment contains elements that could facilitate or restrict participation irrespective of his or her level of function or participation and then correlate this measure with level of disability.

There are a few self-report instruments that use this approach. As a complementary approach to the observational method developed by Shumway-Cook et al. (40), the investigators developed a self-report instrument to ascertain the extent to which people avoided and encountered barriers and facilitators in the physical environment. The self-report approach of Shumway-Cook et al. has been shown to be reliable (40); however, the limitation of this approach is that asking people to ascertain the extent to which they avoid or encounter barriers may not necessarily correspond to what factors are in their environment. For example, if someone with mobility limitations is unable to negotiate stairs, he or she may state stairs are avoided but their environment may not have stairs. In addition, whether people avoid aspects of their environment is likely to be confounded by function; persons will avoid stairs if they are unable to do stairs.

Another means to characterize the environment is to describe the actual elements of the environment. This measurement approach is taken by Keysor et al. in the home and community environment (HACE) (26). The HACE is a 36-item instrument that assesses barriers and facilitators in six conceptual domains: (a) home mobility, (b) community mobility, (c) basic mobility devices, (d) communication devices, (e) transportation factors, and (f) attitudes (26). The community mobility domain assesses the extent to which a person's community has barriers such as uneven sidewalks and curbs without curb cuts. Basic mobility devices, communication devices, and transportation facilitators are assessed to indicate whether the respondent has the device or the type of

transportation irrespective of use. Reliability is acceptable for all subscales. This approach allows the person to characterize the environment irrespective of his or her level of participation or functional ability. The instrument, however, focuses on physical aspects of the environment and as such does not address the broad array of environmental factors articulated by the ICF. In part, this was due to finding poor reliability of items pertaining to policies and services that lead to the items being eliminated during pilot testing and development of the instrument. Fange and Iwarsson took a similar approach by ascertaining people's perceptions of their housing environment such as satisfaction with housing, suitability, security and safety, importance, privacy, social contacts, flexibility, and accessibility (11). Reliability and content validity of the 31-item instrument are acceptable (11).

Applying linking rules between environmental assessments and participation outcomes is appealing; however, no valid approaches are currently identified in the literature. Researchers face several daunting tasks in developing linking rules in the area of participation and environment. First, the ICF currently does not differentiate between activity and participation level outcomes. This makes linking the environment to participation outcomes difficult. Furthermore, the environmental domain of the ICF is not clearly defined. Currently, the environmental domain in the ICF is described in terms of a broad-spectrum of elements ranging from proximal elements such as architectural barriers in one's home, work establishment, or community to distal and diffuse elements such as governmental agencies, informal social networks, and attitudes and ideologies. It is not clear how to best measure aspects of the environment, particularly the diffuse elements such as governmental policies and programs and community attitudes. Third, it is not clear how to measure the environment in the context of how participation evolves. In other words, how does one measure the environment if the environment is a contextual factor that envelops the person and results in participation? Nonetheless, the potential for establishing valid linking rules for this area of the ICF is high and would be useful for clinical practice and research.

In summary, over the past several years, we have seen the development of a new generation of instruments to assess the environment. There are several approaches taken by researchers, with each approach having strengths and weaknesses.

## **LINKS BETWEEN THE ENVIRONMENT AND PARTICIPATION: WHAT DOES THE EVIDENCE SHOW?**

The scientific literature linking the environment to participation among rehabilitation populations is in its infancy. Research over the past several years has advanced conceptual and methodological elements of this complex field of study (41), yet there are still a number of research questions that need to be answered. It is clear, however, that a number of people with mobility

limitations who live in the United States identify barriers and facilitators in their environments (42–45). Some of these barriers are able to be overcome, whereas others are not. In a study of adult wheelchair users in Boston, MA, and Durham, NC, participants reported successful and unsuccessful traveling encounters to a number of community establishments including food stores, restaurants, drug stores, friends or relatives' homes, banks and ATM machines, places for recreation, and doctor's offices (45). A number of barriers were reported during these trips including bad weather or climate, no ramps or ramps that were too steep, no curb cuts or blocked cuts, no parking, no public transportation, small door width, busy traffic, unsafe neighborhoods, and other people's lack of respect and negative attitudes toward wheelchair users (Fig. 18-4). A number of facilitators in the environment were also reported including assistance from other people, accessible transportation, assistive technologies, good weather, curb cuts, and handicap parking. Another population-based study of adults with physical or sensory disabilities showed that 25% of adults with physical or sensory disabilities reported needing home modifications but not having them and having difficulty accessing a health care provider's office because of the physical layout or location of the property and that 13% reported unfair treatment at a provider's office because of disability. Even higher percentages of all of these factors have been reported for people with more disability and lower socioeconomic status (46). These findings are generally supported by other investigators who show that people with mobility limitations report barriers in the built environment, social attitudes, social institutions, cultural norms, and technology domains (42–45) and facilitators in social attitudes, social support, and the availability of technology, devices and products, and accessible transportation (43–45).

A perception of environmental barriers and facilitators does not necessarily link these factors to restrictions or limitations in participation in the complex daily activities of people's lives, nor does it provide definitive proof that these factors are present. To address these limitations, elements of the environment need to be assessed irrespective of functional impairment and the measure needs to be correlated with assessments of participation. There are a few studies that use these approaches though making comparisons is difficult because different assessment instruments are used, different disease adaptation time periods are addressed, and most studies are cross-sectional, limiting the ability to infer causality between the environment and the subsequent disability. Nonetheless, there are several noteworthy findings.

First, Shumway-Cook et al. (40), using an intriguing observational assessment of physical, ambient, and density characteristics of the environment, showed that people with mobility limitations were more likely to use the elevator and less likely to ascend two flights of stairs or walk on uneven surfaces as compared to age-matched persons without mobility limitations. However, there were no differences between groups pertaining to most of the elements of the environment-participation assessment such as average distance walked, street crossings with traffic lights, temperature, light conditions, and level of precipitation. This was an interesting finding because people

**A****B****C**

**FIGURE 18-4.** **A:** Barriers in the human made physical environment: community mobility barriers. **B:** This sidewalk that is under construction presents significant barriers for persons with mobility and visual impairments. **C:** This sidewalk shows a broken, uneven sidewalk that could pose challenges for people who navigate the community using a wheelchair as well as people with walking difficulties and visual impairments.

with mobility limitations reported avoiding long-distance ambulation, crossing streets with traffic lights, crossing busy streets, using stairs and escalators, walking on curbs or uneven surfaces, and going out in icy conditions (40). Thus, in this instance, when actual behavior was observed, there were fewer differences between persons with mobility limitations and those without as compared to self-reported behaviors (25).

Another approach is to correlate self-report assessments of environments with self-report assessments of disability. There are a few studies using this approach, with most showing a small but statistically significant association of the environment with participation. The studies, however, cover an array of patient populations, and more definitive information is needed about the environment-participation relationship. Whiteneck et al. (42), in a large population-based cross-sectional study of 2,726 persons with spinal cord injury, showed that people's perceptions

of barriers in physical, social, and political environmental domains had a small but significant association with participation; however, the scales only accounted for 4% of the variance in participation. Demographics, injury-related factors, and activity limitations each accounted for approximately 20% of the variance in participation. Interestingly, though, environmental factors were more strongly associated with life satisfaction, accounting for approximately 10% of the variance in life satisfaction. Participants in this study, however, had on average at least 3 years of living with their spinal cord injury, and it is possible that participants adapted to their environment and had implemented some accommodations such that their levels of participation were not significantly impaired.

Similar findings are reported among people with traumatic brain injury. Whiteneck et al. (47) in a study of 73 persons with traumatic brain injury found that the environment was

an important determinant of participation. Transportation, the surroundings, government policies, attitudes, and the natural environment were perceived to have the most impact on people's lives. The total CHIEF score and the subscales of attitudes and services, representing higher environmental barrier impacts, were associated with more disability as measured by the overall CHART score. More physical and policy barriers, as measured by two subscales on the CHIEF, were associated with the mobility and occupation subscales of the CHART. More barriers in attitudes and services were associated with less cognitive independence. Rochette et al. (48) in a cross-sectional study of 51 stroke patients selected from a rehabilitation unit showed that environmental barriers had a small but significant relationship with participation, with environmental factors explaining 6% of the variance in participation. Keysor et al. (49) conducted a longitudinal follow-up study of 342 general rehabilitation patients. The investigators showed that a greater presence of barriers in the environment and lower levels of social support were associated with less participation 1 month after discharge from a hospital or rehabilitation center. However, at 6 months after the hospital or rehabilitation center discharge, the only factor in the environment that was associated with participation was social support.

Using neighborhood diversity and density measures, Clark and George (50) reported that neighborhood housing density and land use diversity were not directly associated with disability but did modify the relationship of functional limitation on participation among participants in the 1986 wave of the Duke University site of the Established Populations of Epidemiological Studies of the Elderly (EPESE) project. Specifically, level of dependency in ADL disability and IADL disability was increased among persons with severe functional limitations as the environment became more rural (i.e., less housing density), whereas elderly people with better functional activities reported less ADL disability as the environment became more rural. The authors noted that declining housing density in this population reflected rural versus semiurban living (suburban and city) and hypothesized that rural areas would have less accessible pedestrian and public transportation environments and more substandard housing conditions in comparison to semiurban areas. While use of population housing density could reflect the authors' hypotheses, these measures do not capture environmental factors at the "street level" (e.g., uneven sidewalks, curbs with curb cuts, or buildings without ramps at public entrances) that could be important for disability.

These studies, while providing some evidence that the environment is associated—at least a small amount—with participation, at least in the short term, do not provide an item analysis of which elements of the environment are associated with which elements of participation. In unpublished, preliminary analyses of a large cohort of people with knee and hip osteoarthritis, we found adequate handicapped parking, the ability to drive, and the presence of community parks were associated with greater frequency of participation, while the presence of public transportation was associated with the greater perceived limitation

of participation. Most recently, Wilkie et al. (51) investigated environmental factors associated with restricted mobility outside of the home in 2,252 individuals over the age of 50 with knee pain. Participants were scored as restricted if they replied as getting out of the home as "some," "a little," or "none" in the past 4 weeks. After controlling for knee pain severity, limitations in walking, and demographic and socioeconomic characteristics, authors reported environmental factors including poor access to public transportation and no access to a car were associated with more restrictions in mobility outside of the home.

In sum, findings from the few published studies in the literature provide evidence that the environment in which people live has a significant but seemingly small association with participation. Most of the studies reviewed are cross-sectional, and stronger evidence could be derived from longitudinal and intervention studies. Nonetheless, the studies reviewed in this section use instruments that assess aspects of the community environment. It is unlikely that the degree of barriers or facilitators in the community is confounded by the functional status (or need) of the individual. Assessing characteristics of the community environment and statistically linking them to participation levels in cross-sectional study designs and analyses minimizes confounding by indication and adds validity to cross-sectional findings. Nonetheless, longitudinal studies would provide more definitive results on whether and how the environment impacts disability.

We would like to note, however, that our review is focused on global assessments of the environment as well as more focused assessment of the physical aspect of the environment. Our approach did not include social and social support elements of the community, technology and products, or services, policies, or programs. As identified in the ICF framework, these are important elements of the environment that are presumed to have an impact on participation. Review of them, however, was beyond the scope of this chapter.

## CLINICAL IMPLICATIONS

The rehabilitation field has long underscored the importance of a person's environment on his or her recovery, health status, and participation in daily life activities. Likewise, US government policy has underscored the role of the environment in disability as is evidenced by the 1990 Americans with Disabilities Act (ADA), which protected the rights of people with disabilities by prohibiting discrimination and ensuring equal opportunity and access (52). Since the ADA was instituted, a number of advances regarding environmental accessibility have been achieved. Greater attention is paid to accessibility aspects of public buildings, airlines, subway and bus systems, as well as the technologies and adaptations that are needed for persons with disabilities to pursue employment, housing, and education opportunities.

Theoretical and conceptual frameworks of disability and participation suggest that the environment provides a context to their life situations—that is, participation in complex life

roles is embedded in the environment in which people live. In rehabilitation, this environment is believed to contain a wide array of factors that facilitate or hinder participation. Research supporting these notions in rehabilitation, however, is at its infancy. Nonetheless, the published literature does suggest a small but significant relationship, at least cross-sectionally, between some aspects of the physical environment (e.g., physical, architectural barriers, technologies, and neighborhood characteristics).

So, what clinical implications can we infer from the literature at this point in time? First, *participation* and *environment* are clearly complex, multifactorial, domains that are important yet challenging to assess. Nonetheless, involvement in community-level complex daily activities of people's lives is an important element of rehabilitation, and achieving optimal participation outcomes for rehabilitation populations is critical. Rehabilitation science professionals, therefore, are encouraged to consider participation outcomes as part of routine care for rehabilitation patients.

Second, there is literature that suggests that, at least in the short term, the environment does have an impact on participation. Thus, it seems appropriate for rehabilitation science professionals to ascertain the extent to which environmental barriers and facilitators are present in the environment as a means to help patients optimize participation, at least during initial periods of rehabilitation. It is not, however, entirely clear which elements of the environment are related to participation. There is some research that seems to indicate transportation facilitators are important; however, much more research needs to be done in this area. Nonetheless, the evidence seems to support the notion that the community environment does have an impact on participation. Health care providers, thus, are encouraged to consider the community environment in which people live as it might impact their levels of participation.

Lastly, it is clear that more research is greatly needed in this area of rehabilitation medicine. Stronger research linking the environment to participation and explicating which elements of the environment are influential on participation will be useful to guide clinical intervention and public policy.

# Systems-Based Practice of Physical Medicine and Rehabilitation

The practice of medicine in the United States, as in most nations, is profoundly influenced by government rules, regulations, legislation, and enforcement activity. Governments set standards of professional training, define the scope of practice, authorize individuals to practice, monitor practice performance, and enforce compliance with their standards.

Government also strongly influences the activities of health care providers through certificate of need controls, licensure, and public health requirements. Facilities are subject to many operating rules and requirements, are regularly reviewed, and face many obligations as to how they operate and are reimbursed for the services they provide.

The federal government is the single largest payer for inpatient rehabilitation services (through the Medicare program) and hence has a large impact on all providers and facilities in this segment of the health care industry. Medicare fee-for-service (FFS) beneficiaries account for approximately 70% of inpatient rehabilitation facility (IRF) cases (1), and Medicare spending for IRF services is projected to be \$5.8 billion annually in 2008 and 2009 (2). Medicare actuaries projected \$22.8 billion in spending in 2008 at skilled nursing facilities (SNFs) (3). As a result, the regulations Medicare imposes on providers generally influence practice for all patients, regardless of payer, and become universal standards of compliance.

State governments (in partnership with the federal government) are also very important purchasers of rehabilitation care and services through the Medicaid program. Another dual program of importance, the provision of vocational rehabilitation services, is federally administered by the Rehabilitation Services Administration (RSA) and in each state by its Vocational Rehabilitation Agency.

In addition, government has a central role in assuring protection of patient rights, safety, confidentiality, and non-discriminatory treatment. The legal system addresses quality of care, access to care, and equity.

Compliance with federal regulations is monitored by the Office of the Inspector General of the Department of Health and Human Services (HHS) and the Program Integrity Group of the Centers for Medicare and Medicaid Services (CMS). State Departments of Health typically provide surveillance for compliance with state laws and the Medicaid program.

In this chapter, we describe the various key legal and regulatory features that control and influence the field of physical medicine and rehabilitation (PM&R).

## MEANS OF GOVERNMENTAL INFLUENCE OVER PM&R

As with any regulated field, government influences PM&R through the activities of both the legislative and executive branches. The legislative branch has the sole authority to authorize programs and to appropriate funds. The executive departments and agencies are charged with implementing legislation pursuant to statutory authority, including through agency rulemaking and the enforcement of specific regulatory agendas (4). The statutory basis for a regulation “can vary greatly in terms of its specificity, from very broad grants of authority that state only the general intent of the legislation and leave agencies with a great deal of discretion to very specific requirements delineating exactly what regulatory agencies should do and how they should take action” (5). The executive branch may also propose legislation for the legislative branch to consider.

Because the federal government is the single largest payer for rehabilitation services through the Medicare program, the statutes and regulations that set forth Medicare eligibility and reimbursement policies are of primary importance to the practice of PM&R. The following section provides examples from the Medicare reimbursement system to illustrate the means of governmental influence over PM&R.

## MEDICARE STATUTES AND THE RULEMAKING PROCESS

The Balanced Budget Act of 1997 (BBA) (PL No. 105-133) authorized a number of major structural reforms to the Medicare program, including the transition to prospective payment systems (PPSs) for Inpatient Rehabilitation Facilities (IRFs), SNFs, and Home Health (HH) Care (6). Shortly after enactment of the BBA, the Medicare, Medicaid, and State Children’s Health Insurance Program

(SCHIP) Balanced Budget Refinement Act of 1999 (BBRA) (PL 106-113) and the Medicare, Medicaid, and SCHIP Benefits Improvement and Protection Act of 2000 (BIPA) (PL 106-554) authorized payment for long-term care hospitals (LTCH) based on prospectively set rates. Prior to this transition, PM&R providers were reimbursed retrospectively on a “reasonable cost basis” (7).

These statutes set forth the parameters for each PPS but direct the Secretary of the Department of HHS to implement these payment systems through the rulemaking process. The inpatient rehabilitation facility prospective payment system (IRF PPS), for example, requires providers to be paid predetermined per-discharge rates for “classes of patient discharges...by functional-related groups (each referred to as a “case mix group”), based on impairment, age, comorbidities, and functional capability of the patient and such other factors as the Secretary deems appropriate” (8). The statute also provides for adjustments for area wage variations; individual facility variations; individual patient outliers; lengths of stay; and the annual market basket inflationary update (9). In each case, the statute provides the Secretary with discretionary authority to establish the actual classification system for patients; the weighting factors for expected costliness; the payment rates; the outlier and special payment policies; the area wage adjustments; and the annual update (10). Implementation in these areas involves important methodological considerations and significant determinations as to policy. Express policy objectives set forth in the IRF PPS include providing proper “incentives to furnish services as efficiently as possible without diminishing the quality of the care or limiting access to care” and creating “a payment system that is fair and equitable to facilities, beneficiaries, and the Medicare program” (11).

For each PPS, the Secretary also issues annually a Proposed and Final Rule to implement, refine, and update the reimbursement system for the upcoming fiscal year (FY) in question. The government publishes a notice of each Proposed Rule in the *Federal Register* and solicits stakeholder comments to which it then responds in the Final Rule (12). The FY 2009 Final Rule for the skilled nursing facility prospective payment system (SNF PPS), for example, provides for a 3.4% market basket update to the payment rates used under the SNF PPS and makes certain changes to the case-mix indexes (13).

The annual rulemaking process can lead to significant structural changes in the payment system. As added by the BBA, Section 1886(j) of the Social Security Act confers broad statutory authority upon the Secretary to propose refinements to the IRF PPS; parallel provisions exist with respect to the other PPS. Under this authority, for example, the FY 2006 IRF PPS Final Rule made a number of substantial refinements to the IRF PPS case-mix classification system (the case-mix groups and the corresponding relative weights) and the case-level and facility-level adjustments (14). Further refinements were made in FY 2007 and FY 2008 “to ensure that IRF PPS payments continue to reflect as accurately as possible the costs of care” (15).

## STATUTORY AND REGULATORY DEVELOPMENTS

Despite the basic relationship between the legislative and the rulemaking processes, policy development is almost never a linear process. In the PM&R context, legislation is often a means to alter, suspend, or otherwise supersede regulatory determinations. Legislation is also often a means to temporarily “fix” or “patch” previous laws, or to seek lasting changes in the payment systems. New statutory provisions, moreover, can establish additional regulatory requirements, which themselves must be implemented.

The list of enactments that have significantly impacted the Medicare program, and PM&R in particular, since the passage of the BBA in 1997, include the Medicare, Medicaid, and SCHIP BBRA of 1999 (PL 106-113); Medicare, Medicaid, and SCHIP BIPA of 2001 (PL 106-554); Medicare Prescription Drug, Improvement, and Modernization Act of 2003 (PL 108-173); Deficit Reduction Act of 2005 (DRA) (PL 109-171); the Tax Relief and Health Care Act of 2006 (TRHCA) (PL 109-432); the Medicare, Medicaid, and SCHIP Extension Act of 2007 (MMSEA) (PL 110-173); and the Medicare Improvements for Patients and Providers Act of 2008 (MIPPA) (PL 110-275). Examples of key statutory and regulatory developments follow below.

### The 75 Percent Rule

It has been stated that, “No governmental requirement related to the furnishing of inpatient rehabilitation services has generated more controversy than the criteria for being classified as an inpatient rehabilitation facility—the so-called ‘75 Percent Rule’” (16). In the Final Rule implementing the Tax Equity and Fiscal Responsibility Act of 1982 (TEFRA) in January 1984, the Secretary determined that, to qualify as an inpatient rehabilitation hospital or rehabilitation unit and therefore be distinguished from an acute care hospital, a facility must have “served an inpatient population of whom at least 75 percent required intensive rehabilitation services for one or more of 10 conditions specified in the regulations” within the most recent 12 month cost reporting period (17). The August 7, 2001 Final Rule that implemented the IRF PPS did not change the procedures for classification as an IRF (18). SNFs, by contrast, have no special requirements for offering rehabilitation services. There are also no specific program regulations or requirements for rehabilitation services that may be provided in an LTCH.

On June 7, 2002, the CMS declared a moratorium on enforcement of the 75 Percent Rule because it found the rule was being unevenly enforced by the various state Departments of Health and the Medicare Fiscal Intermediaries (FIs) (19). The moratorium ended in FY 2004 when a new Final Rule for IRF classification was published, which expanded the original 10 conditions to 13 and provided that the 75% compliance threshold was to be phased-in over several years, becoming fully effective for cost reporting periods beginning on or after July 1, 2007. The Final Rule also phased out the use of specific

**TABLE 19.1 The Number of IRF Cases has Declined Since 2004, While Payments per Case have Increased**

TEFRA	PPS							Average Annual Change	
	2001	2002	2003	2004	2005	2006	2007	2002–2004	2004–2007
Medicare spending (in billions)	\$4.51	\$5.65	\$6.16	\$6.43	\$6.40	\$6.29	\$5.95	6.7%	–2.6%
Unique beneficiaries	N/A	398,000	435,000	451,000	410,000	369,000	338,000	6.5	–9.2
IRF patients per 10,000	N/A	114	121	124	112	103	98	4.4	–7.5
FFS beneficiaries									
Cases	415,579	439,631	478,723	496,695	449,321	404,255	370,048	6.3	–9.3
Payment per case	\$9,982	\$11,152	\$12,952	\$13,275	\$14,248	\$15,354	\$16,143	9.1	6.7
ALOS (in days)	14.0	13.3	12.8	12.7	13.1	13.0	13.2	–2.3	1.3

*Note:* IRF (inpatient rehabilitation facility), TEFRA (Tax Equity and Fiscal Responsibility Act of 1982), PPS (prospective payment system), N/A (not available), FFS (fee-for-service, ALOS (average length of stay).

*Adapted from Medicare Payment Advisory Commission March 2009; MedPAC Report to Congress.*

patient comorbidities as counting toward the required 75% compliance threshold (20).

Implementation of the revised 75 Percent Rule created a serious barrier to access to PM&R services for patients in inpatient rehabilitation hospitals and units as seen in Table 19-1.

This table makes it clear that there was a dramatic drop in the number of cases admitted to rehabilitation hospitals and units, and an increase in length of stay and payment per case which represents the more severely medically and functionally impaired patients who were admitted.

It spawned intensive legislative advocacy. In the DRA of 2006, Congress responded and delayed implementation of the 75 Percent Rule by 1 year (21). After that moratorium expired, Congress subsequently passed the MMSEA of 2007, which indefinitely set the compliance threshold at 60% (22). MMSEA also provided that patient comorbidities be permanently included in the calculations used to determine whether an IRF meets the compliance percentage. With this legislative provision in place, the focus then turned to implementation of the new 60 Percent Rule (23). As a trade-off for achieving permanent relief on the 75 Percent Rule by establishing a statutory 60% compliance threshold, the field of medical rehabilitation experienced an adverse economic consequence when the MMSEA rolled back the IRF update factor to 0% in FY 2008 and held it a 0% for FY 2009. Freezing or reducing updates has become an increasingly prominent means of seeking Medicare cost savings (24).

### Payment Updates and Other Payment System Changes

Under the various PPS, and under the Physician Fee Schedule (PFS) for professional services provided under Part B of the Medicare program, reimbursement rates are to be updated annually. The update calculation is made during the rule-making process based on the index or process provided for in the underlying statute. Commonly, however, legislation

is proposed and enacted as a means to override the update formula or amount. Section 131 of the MIPPA of 2008, for example, substituted a positive update of 1.1% to payment rates under the Medicare PFS for the negative update that would have resulted from the application of the statutory formula.

### Outpatient Therapy Caps

As a cost control measure, Section 4541 of the BBA of 1997 required the CMS to impose a cap on Medicare outpatient rehabilitation therapy services for outpatient physical, speech-language and occupational therapy services by all providers other than hospital outpatient departments. Because of their complexity and direct harm to Medicare beneficiaries, the therapy caps have been subject to a “series of moratoria” enacted by Congress to avoid the strict limit placed on access to outpatient rehabilitative care (25). Most recently, Section 141 of MIPPA extended the exceptions process for therapy caps at least through December 31, 2009.

### Medicare Recovery Audit Contractors

The Medicare Modernization Act of 2003 (MMA) established the Recovery Audit Contractors (RAC) program as a demonstration program to identify improper Medicare payments. The TRHCA of 2006 made the RAC program permanent and directed the CMS to expand the program to all 50 states by 2010. The RAC demonstration program as implemented in California by the contractor, PRG Shultz, resulted in numerous coverage denials based upon medical necessity reasons. Subsequently, the affected California providers appealed these denials and a large percentage (90%) of these denied coverage decisions were reversed when they were appealed, based on anecdotal reports from California IRF providers. Specifically, 6% of the overpayments collected under the demonstration program through March 27, 2008 were from IRFs (26). Of those cases, 94% were deemed medically unnecessary services or settings (27). The number of claims

in California with overpayments less cases overturned on appeal as of March 27, 2008 was over 4,480 (28). However, upon a subsequent review by a different CMS contractor, nearly 40% of the cases denied by the California RAC demonstration contractor were found to be incorrect (29). In implementing the program nationwide, CMS regulations relating to medical necessity denials and appeals remain a key issue (30). Legislation was introduced in the 110th Congress to impose a moratorium on the nationwide rollout of the RAC program but did not advance (31). Legislation requiring enhanced oversight and accountability of RACs is anticipated in the 111th Congress.

### Quality of Care

As part of ongoing initiatives to refocus payment incentives toward quality, CMS has already implemented a “pay for reporting” system for physicians where payment rates are tied to the reporting of quality measures. MIPPA made the Physician Quality Reporting Initiative permanent and authorized incentive payments through 2010. A potential next step is “pay for quality” where “providers would not only be rewarded for reporting quality activities but their payment would also be increased or decreased depending on how well they perform on these quality measures” (32). Given the pervasive influence of the Medicare program, any such reimbursement mechanism can be expected to influence practice for all patients, regardless of payer. Payment system reform will likely include enhanced performance outcome measurements applicable to rehabilitation and LTCH.

## THE PERVASIVE INFLUENCE OF MEDICARE AND MEDICAID

Given their scope of coverage, the Medicare and Medicaid programs have a profound influence on the practice of PM&R. This section sets forth the structure and features of each program.

### The Medicare Program

Prior to the passage of the Medicare program, physicians practiced primarily in their offices and some in the hospitals and units providing medical rehabilitation services. Payment came from some insurance companies, private pay, and some state programs (33).

The original Medicare and Medicaid programs were enacted in 1965 through Titles XVIII and XIX, respectively, of the Social Security Act. The Medicare system was originally administered by the Social Security Administration, but in 1977 management was transferred to the Health Care Financing Administration, which was renamed the CMS in 2001. CMS is part of the U.S. Department of Health and Human Services and maintains a Web site at [www.cms.hhs.gov](http://www.cms.hhs.gov).

Beneficiaries become eligible for Medicare by virtue of age (65 or older), disability, or if they have end-stage renal disease (ESRD) (34). Medicare has four parts which describe

**TABLE 19.2 Medicare enrollment**

	Medicare Enrollment (enrollees in millions)			
	2007	2008	2009	2009 +/-2008
Aged	36.7	37.4	38.1	-0.7
Disabled	7.2	7.3	7.4	-0.1
<b>Total Beneficiaries</b>	<b>43.9</b>	<b>44.6</b>	<b>45.5</b>	<b>+0.8</b>

and cover various aspects of the program. Medicare Part A and Part B are referred to as the original Medicare program, or the FFSs program. Medicare Part C is known as Medicare Advantage (MA) and gives beneficiaries the option to receive their Medicare benefits through managed care and private health insurance plans. Medicare Part D provides a prescription drug benefit (35).

The programs have grown exponentially since inception. Short-term Medicare growth is reflected below (Table 19-2).

Medicare payments for federal FY 2009 were estimated in the President's FY 2009 budget at \$485.9 billion. The chart below displays the Medicare payments, known as outlays, estimated for FY 2009 (Fig. 19-1).

### Medicare Part A

Medicare Part A, in general, covers inpatient hospital services, critical access hospitals, SNFs (not including custodial or long-term care), hospice care, and the Part A portion of HH care and services. Part A thus covers the services provided in inpatient medical rehabilitation hospitals and units, long-term acute care hospitals, psychiatric hospitals, cancer hospitals, and children's hospitals (36).

People with over 40 quarters of covered employment are entitled to Part A without paying a premium, but most covered services require a beneficiary co-payment or coinsurance (37).

**FIGURE 19-1.** Medicare outlays by service.

In 2009, beneficiaries paid a \$1,068 deductible for a hospital stay of 1 to 60 days and \$133.50 daily coinsurance for days 21 to 100 in an SNF (38). Part A is financed through a payroll tax.

The Social Security Act also provides for the enrollment, subject to payment of a monthly premium, of individuals who do not meet the requirement of 40 quarters of covered employment and are not otherwise eligible (39). CMS estimates that approximately 588,000 enrollees voluntarily enrolled in Medicare Part A by paying a monthly premium of \$433 for CY 2009 (40).

Under Part A, providers are paid on the basis of a PPS specific to that provider. For example, acute care hospitals are paid per discharge under the inpatient prospective payment system (IPPS) using a classification system called Medicare Severity Diagnosis Related Groups (MS-DRGs) based on data from a series of ICD-9-CM codes (41). Notably, on January 16, 2009, the Department of HHS published the Final Rule on the adoption of ICD-10-CM, the new diagnosis coding system that is being developed as a replacement for ICD-9-CM with a compliance date of October 1, 2013 (42).

Inpatient rehabilitation hospitals and units are paid per discharge through the IRF PPS using a classification system known as Case Mix Groups (CMGs) which are derived from information collected on the inpatient rehabilitation facilities patient assessment instrument (43). SNFs are paid on a per diem basis under the SNF PPS, using a classification system known as the Resource Utilization Groups which are based on information taken from the data collection instrument known as the Minimum Data Set (44). Home health agencies (HHA) are paid per episode on the basis of the home health prospective payment system which uses a classification system known as the home health resource groups which are derived from information on the data collection known as the Home Health Outcome and Assessment Information Set (45).

LTCHs are paid also on a per-discharge basis through the long-term care prospective payment system using a case mix classification system known as the Medicare Severity Long-Term Care Diagnosis Related Groups. However, like the acute inpatient hospitals, there is no separate patient assessment instrument. The information entered on the billing—specifically the ICD-9-CMs—determines the MS LTC DRG which specifies the payment rate.

In policy arenas, each payment system and provider is referred to as a “silo of care.” There is growing interest in consolidating these into one PPS. The Post Acute Care Reform Plan developed by CMS sets an “ultimate goal of site neutral payment for PAC [postacute care] services” (46).

In addition, in December 2008, the Congressional Budget Office (CBO) released *Budget Options Volume I: Health Care*. This document outlines a number of proposals for reforming Medicare. Option 30 proposes to bundle payments for hospital and postacute care. Under this option, Medicare would pay a single, bundled rate to an inpatient hospital that includes the cost of postacute care based on the average cost for a specific MS-DRG across all current postacute settings (47).

This option is projected to save the Medicare program nearly \$19 billion over the 10-year budget window. This proposal was echoed in the President’s FY 2010 Budget Outline, *A New Era of Responsibility: Renewing America’s Promise* (48). The significance of these developments is discussed further below.

### Medicare Part B

Part B of Medicare is known as Supplementary Medical Insurance. It covers physician services including all specialty areas (49). Physician services are paid on the basis of the PFS (50). Physical therapists, occupational therapists, and speech-language pathologist services are also covered under Part B and paid under the PFS (51). Part B additionally covers outpatient services such as the therapy services mentioned above and other outpatient services including certain laboratory services, preventive exams and screening, shots, durable medical equipment, prosthetics and orthotics and supplies, comprehensive outpatient rehabilitation facilities, and certain HH care services (52). Hospital outpatient services are paid on a separate outpatient prospective payment system using a classification system known as Ambulatory Patient Classifications, which combines services that are clinically similar and similarly resource-intensive (53). Durable medical equipment is paid according to a fee schedule separate from the PFS (54).

Part B coverage is voluntary and about 93% of Medicare beneficiaries are enrolled in it (55). Approximately 25% of Part B costs are financed by beneficiary premiums, with the balance being covered by the government’s general revenue funds (56). The standard monthly premium was \$96.40 for CY 2009, but premiums increase at higher levels of adjusted gross income (56).

### Medicare Part C

Medicare Part C is known as the MA Program. It is the third in a series of iterations on Medicare managed care plans and programs. The BBA of 1997 first established a new “Part C” in the Medicare statute which provided for a Medicare + Choice program (57). Title II of the Medicare Prescription Drug Improvement and Modernization Act of 2003 made revisions to the existing provisions in Medicare Part C, establishing what is now called the MA program (58). The MA program allows Medicare beneficiaries to receive their Medicare benefits from private plans rather than from the traditional FFS program (59). Plans may offer additional services and benefits, which may be reflected in the plan’s monthly premium (59).

Only people who have both Medicare Part A and Medicare Part B are eligible to join an Advantage Plan. Under § 1851(a)(1) of the Social Security Act, as modified by § 201 of the MMA (“Implementation of Medicare Advantage Program”), every individual entitled to Medicare Part A and enrolled under Medicare Part B, except for most individuals with ESRD, may elect to receive benefits through either the original Medicare program or an MA plan. In 2008, about 22% of beneficiaries were enrolled in an advantage plan and there was a continuing trend upward in enrollment (59). Technically, Medicare beneficiaries participating in an MA plan are to be able to receive

all regularly covered Medicare services, rights, and protections (59). However, one constant concern in the medical rehabilitation community is that these plans do not provide all of the covered services, especially inpatient hospital-level rehabilitation services. Specifically, MA plans have been prone to sending many traditional inpatient rehabilitation patients such as stroke patients and orthopedic patients to SNFs for care.

There are several types of plans. They include traditional Medicare Health Maintenance Organizations (HMOs), Medicare Preferred Provider Organizations (PPOs), Medicare Private Fee-for-Service (PFFS), Medicare Special Needs Plans (SNP), and Medicare Medical Savings Accounts (MSAs). Additionally, there are Medicare Cost Plans that are similar to HMOs, with the exception that services received outside the plan are covered under the Original Medicare Plan. There are also demonstration and pilot programs and the Program of All Inclusive Care for the Elderly (60).

### Medicare Part D

Medicare Part D is a voluntary, outpatient prescription drug benefit. It was created by the Medicare Prescription Drug Improvement and Modernization Act of 2003 and represents the largest expansion of the Medicare program since its original enactment.

There are two ways of receiving benefits under Part D: (a) through a stand-alone Medicare Prescription Drug Plan which adds drug coverage to Original Medicare, some Medicare Cost Plans, some Medicare PFFS Plans, and Medicare MSA Plans; or (b) through Medicare Advantage-Prescription Drug plans that offer Medicare prescription drug coverage through the MA plan along with Part A and Part B coverage (61).

Under the 2009 standard drug benefit, beneficiaries pay a monthly premium plus a \$295 deductible, after which Medicare covers 75% of allowable drug expenses up to a benefit limit of \$2,700. At this point, there is a “coverage gap” where the beneficiary pays out-of-pocket until the catastrophic limit of \$4,350 is reached, at which point Medicare covers subsequent expenditures with a 5% beneficiary coinsurance (62). Private plans can make different provisions for the coverage gap (62). This so-called “donut hole” in coverage is a controversial aspect of the Part D program.

### Medicaid

The Medicaid Program provides medical benefits to groups of low-income people, some who may have no medical insurance or inadequate medical insurance. Although the federal government establishes eligibility and general guidelines, the Medicaid program requirements are actually established by each state. The range of benefits a person is eligible for under Medicaid depends on the state in which he or she lives. States are required to include certain types of individuals or eligibility groups under their Medicaid plans. They may include other groups as well. Eligibility groups are referred to as categorically needy, who are required to be covered; medically needy, who may be covered at the state's discretion; and special groups (Table 19-3) (63).

**TABLE 19.3 Medicaid enrollment**

	Medicaid Enrollment (enrollees in millions)		
	2007	2008	2009
Aged 65 and over	5.0	5.1	5.2
Blind and Disabled	8.5	8.6	8.7
Adults	11.1	11.3	11.5
Children	23.5	24.0	24.4
Territories	1.0	1.0	1.0
<b>Total</b>	<b>49.1</b>	<b>50.0</b>	<b>50.8</b>

Categorically needy people are

- Families who meet states' Aid to Families with Dependent Children eligibility requirements in effect on July 16, 1996
- Pregnant women and children under age 6 whose family income is at or below 133% of the Federal poverty line
- Children aged 6 to 19 with family income up to 100% of the Federal poverty level
- Caretakers (relatives or legal guardians who take care of children under age 18 [or 19 if still in high school])
- Supplemental Security Income (SSI) recipients (or, in certain states, aged, blind, and disabled people who meet requirements that are more restrictive than those of the SSI program)
- Individuals and couples who are living in medical institutions and who have monthly income up to 300% of the SSI income standard (Federal benefit rate) (63)

Medically needy people fall above the income and resource threshold to be eligible as categorically needy. If a state has a medically needy program, it must include pregnant women through a 60-day postpartum period, children under age 18, certain newborns for 1 year, and certain protected blind persons (64).

States may also, at the state's option, provide Medicaid to a number of other groups based on medical necessity, including

- Blind persons (blindness is determined using the SSI program standards or state standards)
- Disabled persons (disability is determined using the SSI program standards or state standards) (65)

The Medicaid program may also include various special groups such as

- Qualified Medicare Beneficiaries
- Qualified Working Disabled (66)

States are required to offer certain services, such as inpatient hospital services, and may offer others. However, since states have a large degree of discretion, coverage of medical rehabilitation services varies widely, including coverage of inpatient rehabilitation hospital services. Medicaid coverage of rehabilitation services has been the subject of considerable regulatory and legislative activity in recent years (67). In August 2007, CMS issued a proposed rehabilitation services rule to

more clearly define the scope of the rehabilitation benefit; identify services that could be claimed as rehabilitation under Medicaid; and ultimately reduce federal Medicaid spending for rehabilitative care (68). Implementation of this Final Rule has been delayed by several legislative moratoria, including a provision contained in the landmark economic stimulus legislation passed in 2009.

### State Children's Health Insurance Program

In addition to a state's Medicaid program, states have a health insurance program for children up to age 19, known as the SCHIP. SCHIP was created under the BBA of 1997 as Title XXI of the Social Security Act (69). In some states, SCHIP is part of the state's Medicaid program; in other states it is separate; and in some states it is a combination of both types of programs. These programs are for children whose parents' income is too high to be eligible for Medicaid but not high enough to buy private insurance. Not all the insurance programs provide the same benefits, but they all include immunizations and care for healthy babies and children at no cost. Families may have to pay a premium or a small co-payment for other services depending on their income (70).

## OTHER GOVERNMENTAL PROGRAMS

Other federal and state programs also pay for various levels of medical rehabilitation services. It is important that a practitioner be aware of these for reference. They are described briefly here.

### Vocational Rehabilitation

The Rehabilitation Act of 1973 (PL 93-112), as amended, is the major legislative source for programs and initiatives administered by the RSA (71). Title I establishes the state vocational rehabilitation programs and agencies. These programs are paid for by a combination of state and federal funds (71).

State vocational rehabilitation agencies must, at a minimum, provide evaluations of rehabilitation potential, including diagnostic and related services; counseling, guidance, referral, and placement services; and vocational and other training services to enhance the employability of eligible individuals (72). They also must provide a variety of other services, including physical and mental restoration services, if comparable services and benefits are not available under any other program (72). Restoration has historically included a broad range of medical and healthcare services, including medical rehabilitation services (72). Success for a counselor working for a state agency is usually determined by the number of successful case closures for individual clients, which may mean gainful employment, entering a training program, participating in special programs, or returning to living in the community (73).

### Workers Compensation

Workers' Compensation (WC) laws focus on ensuring that employees who are injured or disabled in the course of their employment are provided with medical care, rehabilitative

services, and fixed monetary awards, eliminating the need for prolonged litigation. Some laws also protect employers and fellow workers by limiting the amount an injured employee can recover from an employer and by eliminating the liability of co-workers in most accidents. Contrary to general medical insurance, the focus here is on returning employees to work, and there is a strong incentive to provide rehabilitation services.

The first workers' compensation program was established by the federal government for sectors of its civilian workforce in 1908, which was then expanded to cover essentially all civilian Federal employees through the Federal Employee's Compensation Act (FECA) of 1916 (74). There are now multiple separate nonfederal workers' compensation programs, one in each state, plus the District of Columbia, Puerto Rico, and the Virgin Islands. The Office of Workers' Compensation Programs (OWCPs) within the U.S. Department of Labor provides a survey state workers' compensation laws (75). There are also federal workers' compensation programs which are mentioned below.

The basic concept underlying the workers' compensation laws is to provide a mechanism for alternative dispute resolution at the workplace, thereby relieving employers of liability for negligence and relieving employees of the need to initiate lawsuits in order to receive any compensation for injuries. Considerable variation exists among programs based upon the state or territorial law.

The definition of disability used in workers' compensation programs is generally less restrictive than that employed in the federal disability programs (SSDI/SSI). Generally, individuals claiming workers' compensation benefits must show only that they are unable to perform their former employment or to obtain employment suitable to their qualifications and training. Although workers' compensation benefits were originally intended largely for victims of industrial accidents, in recent years, workers' compensation laws have been broadened to cover individuals who have occupational diseases as well (76).

Although all workers' compensation programs provide coverage for medical services and medical rehabilitation services, the use of such services can be problematic where the employer and the employee contest a benefit claim. In such cases, the employee may perceive a strong incentive to maintain his or her "disabled" status by not actively participating in rehabilitation activities. Similarly, in certain circumstances, the relatively high weekly wage replacement benefits may also act as a disincentive to their acceptance of the rehabilitation services that might assist them to return to work.

The Department of Labor's OWCP administers four major disability compensation programs which provide wage replacement benefits, medical treatment, vocational rehabilitation, and other benefits to federal workers or their dependents who are injured at work or acquire an occupational disease (77). The Federal Employers' Liability Act (FELA) and Merchant Marine Act (which essentially extended FELA to sailors) protect railroad workers and merchant marines and are discussed below.

The Federal Employees' Compensation Act (FECA) provides workers' compensation for nonmilitary federal employees (78). Many of its provisions are typical of most state worker compensation laws. Awards are limited to "disability or death" sustained while in the performance of the employee's duties due to injury or disease, but not caused willfully by the employee or by intoxication. The Act covers medical expenses due to the disability and may require the employee to undergo rehabilitation and/or job retraining. A disabled employee receives two thirds of his or her normal monthly salary during the disability and may receive more for permanent physical injuries, or if he or she has dependents. The Act provides for compensation for the survivors of an employee who is killed. The Act is administered by the OWCPs.

The OWCPs also administer the following disability benefit laws. Congress enacted the Longshore and Harbor Workers' Compensation Act (79) to provide workers' compensation to specified employees of private maritime employers. The Black Lung Benefits Act (79) provides for workers' compensation for miners suffering from "black lung" (pneumoconiosis). The Act requires liable mine operators to pay disability payments and establishes a fund administered by the Secretary of Labor to provide disability payments to miners when the mine operator is unknown or unable to pay. The Energy Employees Occupational Illness Compensation Program Act (80) provides benefits to employees and qualified survivors of the Department of Energy and its contractors who developed radiation-related cancer, chronic beryllium disease, or chronic silicosis. Monetary and medical care compensation is only available to people and their survivors who worked or were exposed at certain facilities during specific time periods.

The Federal Employers' Liability Act (FELA) (81), while not a workers' compensation statute, provides that railroads engaged in interstate commerce are liable for injuries to their employees if they have been negligent. The Merchant Marine Act (the Jones Act) (82) provides seamen with the same protection from employer negligence as FELA provides railroad workers.

### **Veterans Administration for Discharged Veterans**

The mission of the Veterans Healthcare System is to serve the needs of America's veterans by providing primary care, specialized care, and related medical and social support services, as defined by the Veterans Administration (83). To accomplish this mission, the Veterans Health Administration (VHA) created an integrated healthcare system. The VHA has multiple offices, including the Office of Patient Care Services and the Office of the Assistant Deputy Undersecretary of Health (84).

The Office of Patient Care Services houses VHA's clinically related programs that support the actual delivery of patient care services in the field (85). The office "integrates professional knowledge and practice skills into policy, planning, and systemwide development of patient care guidelines, critical pathways, and practice parameters" (85). The office is organized "around 13 substantive, cross-functional strategic health

care groups," that replaced a "traditional 'stovepipe' structure organized around discrete professions and disciplines" (85).

The Office of the Assistant Deputy Under Secretary for Health acts as "an advisor for development, implementation, and impact of VHA policy, strategic planning, and knowledge/data management ('Turning Information Into Insight') in support of the offices of the Under Secretary for Health and Deputy Under Secretary for Health (85). The Office contains four central offices and two field-based groups that "coordinate various aspects of VHA's national policy development and strategic planning initiatives" (85).

Under the VA system, virtually all types of inpatient and outpatient care, including medical rehabilitation services, are covered for eligible veterans. Services are usually administered at a VA health care facility. If a particular facility is fully occupied, priority is given to veterans according to their VA priority group, irrespective of severity of illness or disability (except in the case of emergencies). Occasionally, when warranted by special circumstances, the VA authorizes payment for hospital care at a non-VA facility.

In 2004, VA established four special Polytrauma Rehabilitation Centers that focus on the injuries active duty personnel experienced in the Iraq and Afghanistan wars (86). A fifth center is scheduled to open in San Antonio, Texas, in 2011 (86). VA recognizes polytrauma as "one of several 'signature injuries' for veterans of Iraq and Afghanistan. Polytrauma care includes "injuries to more than one physical region or organ system, one of which may be life threatening, and which results in physical, cognitive, psychological, or psychosocial impairments and functional disability," including traumatic brain injury, hearing loss, amputations, fractures, burns, and visual impairment (86).

### **TRICARE and the Military Health Care System for Active Duty, Retired, and Discharged Service Personnel**

TRICARE is the Department of Defense's health care program for "serving active duty service members, National Guard and Reserve members, retirees, their families, survivors, and certain former spouses worldwide" (87). It pays for medically necessary services and supplies, including rehabilitation therapy to improve, restore, or maintain function, or minimize deterioration of function. The "treatment must be medically necessary and appropriate medical care," and must be "rendered by an authorized provider, necessary to the establishment of a safe and effective maintenance program in connection with a specific medical condition, provided at a skilled level, and must not be custodial care or otherwise excluded from coverage" (88). Providers can contract with the regional TRICARE contractor which then negotiates rates with providers. During the course of treatment, a single patient may be involved with TRICARE, the VA, and Medicare which can cause strain and confusion among providers and patients, and their families who must navigate among the various systems. To address such issues, the Bush Administration established a Commission on Care for America's Returning Wounded Warriors in 2007 which recommended restructuring of these systems (89).

## Public Health Service

The Office of Public Health and Science (OPHS) within the Department of HHS is composed of “12 core public health offices and the Commissioned Corps, a uniformed service of more than 6,000 health professionals who serve at HHS and other federal agencies” (90). The Assistant Secretary for Health oversees the OPHS and is the primary advisor to the Secretary of HHS on public health matters (90). The Office of the Surgeon General, under the direction of the Surgeon General, “oversees the operations of the 6,000-member Commissioned Corps of the U.S. Public Health Service” (91). The Surgeon General “serves as America’s chief health educator by providing Americans the best scientific information available on how to improve their health and reduce the risk of illness and injury” (91).

The Indian Health Service (IHS) is part of the U.S. Department of Health and Human Services and is responsible for providing federal health services to American Indians and Alaska Natives. The IHS currently provides health services to approximately 1.9 million of the 3.3 million American Indians and Alaska Natives who belong to more than 562 federally recognized tribes in 35 states (92). The agency FY 2008 budget was \$3.35 billion (93).

The IHS provides health care to Native Americans and Alaska Natives at 31 hospitals, 50 health centers, and 31 health stations (92). Thirty-four urban Indian health projects supplement these facilities with a variety of health and referral services (92). The IHS employs approximately 2,500 nurses, 850 physicians, 40 engineers, 500 pharmacists, and 300 dentists, as well as other health professionals totaling more than 15,000 in all (92).

## PRIVATE PAYERS OF MEDICAL REHABILITATION SERVICES

Although the private sector finances fewer medical rehabilitation services than does the public sector, it plays an important role in the financing of medical rehabilitation services. The private sector payers of rehabilitation include health insurers, disability insurers, prepaid managed care providers, self-insured employers, and casualty insurers.

There are two general types of insurance in the private sector, each of which has a different orientation to medical rehabilitation services. They are

- Life, health, and disability insurance, which provide coverage for the insured individual and typically the individual’s family
- Property and casualty insurance (including workers’ compensation, automobile liability, automobile no-fault, personal liability, and general liability), which provides coverage for injuries to individuals other than the insured

With the exceptions of life insurance and property insurance (which typically do not cover the costs of disability), private sector insurance also plays a role in paying for medical

rehabilitation services. Based on known governmental payments through the Medicare and Medicaid programs, private sector insurers (including Blue Cross/Blue Shield, HMOs, PPOs, PPAs, workers’ compensation plans as mentioned above and other “commercial insurance”) in the aggregate account for approximately 30% to 40% of all inpatient rehabilitation hospital revenues.

Unfortunately, many private sector payers have not embraced the full scope of medical rehabilitation services, both inpatient and outpatient. Thus, they offer a broad variety of medical rehabilitation benefits; at one end of the spectrum from zero medical rehabilitation coverage to full coverage of all medical rehabilitation services with comprehensive case management. Each type of payer has different obligations and different incentives to cover medical rehabilitation services.

## Health and Disability Insurance

Of the two general types of private sector insurance discussed above, health and disability insurance pays the largest percentage of medical rehabilitation costs (94). Health insurance pays for medical rehabilitation services to the extent that such services are covered in the insurance contract between the insurer and the insured, usually an employer and the insurance company.

Disability insurance compensates insured employees and their families for lost income resulting from a disability that prevents the employee from engaging in the occupation held at the onset of the disability (94). Like health insurance, coverage under disability insurance is dictated by the provisions of the contract between the insurer and the insured. Unlike health insurance, disability insurance contracts typically do not formally cover the costs of medical care, such as medical rehabilitation, since it is primarily an income replacement program. Despite this, some long-term disability insurance plans have paid for medical rehabilitation services on an ad hoc, extracontractual basis in order to return the enrollee to work as soon as possible (95).

The two types of health insurance most relevant to the financing of medical rehabilitation are (a) primary hospitalization and (b) major medical insurance. Primary hospitalization pays the cost of covered hospital bed and ancillary services up to prescribed limits. In cases that require extended acute hospital stays, such as spinal cord injury and head injury, hospitalization insurance is often exhausted by the time the individual is medically stable enough to start rehabilitation. Major medical insurance, which provides broad and substantial coverage for large, unpredictable medical expenses, then pays for the remainder of covered services (up to prescribed ceiling, if any).

Due to the high costs of trauma care, posttrauma acute care, and medical rehabilitative care, a health insurance policy that does not include a substantial major medical component for catastrophic illness or injury is not likely to provide adequate coverage for comprehensive medical rehabilitation services or extended rehabilitation services. Therefore, the prevalence of major medical insurance, to the extent that such policies cover medical rehabilitation, is particularly relevant in considering the financing of rehabilitation services.

## STATE LEGISLATIVE AND REGULATORY ASPECTS OF PM&R PRACTICE

### Professional Licensing

In contrast to the national programs of voluntary certification by specialty boards (such as the American Board of Physical Medicine and Rehabilitation), medical licensure is administered by each state. State laws define the scope of practice for physicians, as well as all other licensed independent practitioners (such as psychologists, physician assistants nurses, advanced practice nurses and nurse practitioners, podiatrists, pharmacists, physical therapists, occupational therapists, chiropractors, and many other professionals). Practice laws may be amended from time to time, and many professions seek to change the limits and scope of their practices by lobbying for changes to these laws (96).

State licensing authorities generally are organized to have a governing body of appointed professionals or other stakeholders, and a full-time staff (97). These agencies administer the regulations around licensure and handle tasks such as verifying credentials and training, assessing practitioner competency (through administration of tests or acceptance of other standardized measures), and monitoring ongoing practice. Many states use their licensing authorities to capture data about practitioners and to enforce training in professional areas deemed to be important, such as risk management, cultural sensitivity, and other topics.

State licensing authorities also oversee programs for practitioners who run afoul of proper practice, violating professional standards of practice, or laws (97). Licensing authorities enjoy the authority to restrict a practitioner's activities or to revoke a license in order to protect the citizens of the state.

### Facility Definitions and Licenses

Organizations that seek to deliver health care services generally need to be licensed to do so by the state. Many states also control the health care market by maintaining Certificate of Need or Determination of Need laws (and agencies to administer them) that regulate or restrict the number of beds or facilities that may operate, and also control expansion and significant renovation expenditures (98). Rehabilitation hospitals and outpatient units are subject to scheduled and unscheduled surveys by the state. Unscheduled surveys may be random or as a result of a complaint or allegation of deficiency. In general, when a hospital is found to have operating deficiencies, it is given an opportunity to appeal the findings and to remediate the problems. In the extreme, the state has the authority to prevent the entity from admitting new patients, or even operating, and may impose monetary fines on the owners for certain violations.

### Corporate Practice of Medicine Laws

A number of states have laws controlling or preventing the employment of physicians and other professionals by corporations, under the theory that their independent practice judgment could be compromised by obligations imposed by

a corporate employer. These laws generally do not apply to not-for-profit corporations or professional practice corporations. In states with strong corporate practice of medicine laws, there may be few to none facilities operating that are structured as for-profit enterprises (99).

### Professional Liability Insurance

Malpractice insurance is usually desired by practitioners and rehabilitation hospitals to protect them from adverse judgments in liability suits. Premium rates are influenced by the specialty, local market, individual state's Insurance Commissioner or agency, and the history of paid claims in the state. In many states, strong economic incentives appeal to plaintiff attorneys (who may be working under a contingency fee arrangement and could receive one third of any award) to encourage filing malpractice suits. States that have passed laws to cap awards in some manner generally have more modest premium rates than those with unconstrained systems (100).

### The Federal Budget Process

The annual federal budget process dictates the approach to the appropriated and the entitlement programs. Annual appropriations are necessary to fund several key PM&R programs, including funding for health research and related demonstration projects. The federal budget process distinguishes between "discretionary" or "appropriated" programs and "mandatory or entitlement programs" (101). Mandatory or entitlement spending has its legal basis in previously enacted statutes that provide spending automatically, as for eligible beneficiaries of the Medicare and Medicaid programs. Congress can affect spending on entitlement programs by changing eligibility requirements or the structure of programs through the authorizing legislation. Such changes to "direct" spending are under the jurisdiction of the authorizing, not the appropriating, committees.

Hence, Medicare and Medicaid, as entitlement programs, are not controlled by annual appropriations but can be altered through changes to the authorizing legislation (101). For example, the President's FY 2009 Proposed Budget included Medicare legislative proposals with estimated savings of \$12.2 billion in FY 2009 and \$178 billion over the 5-year budget window, achieving those savings through reductions in many of the Medicare payment updates (102). The above referenced Budget Outline for FY 2010 references Medicare and Medicaid proposals with an estimated savings of \$1.8 billion for FY 2010 and of \$316.005 billion over 10 years.

The federal budget process is controlled by a series of procedures set forth in Titles I through IX of the Congressional Budget and Impoundment Control Act of 1974 ("Congressional Budget Act"), as amended (103). The process begins with the submission in early February of the President's Proposed Budget request to the Congress. The President always presents the recommended annual budget for the next upcoming FY which begins on October 1 of any year (e.g., FY 2011 begins on October 1, 2010 and ends on September 30 of the subsequent year). The President's FY 2010 Budget released in

February 2009 proposed spending for departments and agencies beginning on October 1, 2009. The House and Senate Budget Committees use the President's budget request as a starting point to draft what is known as the "Budget Resolution." Unlike an ordinary bill, the Budget Resolution is a "concurrent" Congressional resolution, and therefore does not require a Presidential signature or veto. It also requires only a majority vote to pass and cannot be filibustered in the Senate (104).

The Congressional Budget Resolution sets spending targets in each of 19 broad spending categories (known as budget "functions"). Those amounts are then allocated to the corresponding Congressional Committees and Subcommittees through two processes—known as 302(a) and 302(b), respectively, and serve as the target for discretionary programs under their jurisdiction. With respect to the annual appropriations process, the Appropriations Committee receives a single 302(a) allocation and decides upon the 302(b) allocations to the Subcommittees with jurisdiction over each of the annual appropriations bills (105).

The Budget Resolution is often little more than a "target" for the appropriators and can readily be exceeded or bypassed. The House and Senate each pass separate Budget Resolutions and attempt to reconcile differences and reach a final Conference agreement which then is passed by both Houses typically by late March. A number of times Congress has actually failed to reach agreement on a Budget Resolution and the legislative process typically proceeds. For example, a final Budget Resolution was never adopted or enacted by Congress for FY 2009.

Appropriators and authorizing Committees enjoy the authority to make precise determinations of levels of funding and/or budgetary cuts to departments and agencies within their respective jurisdictions. The aggregate spending allocations for discretionary spending serve only as an internal control, enforceable through "points of order" and other procedural mechanisms. The Budget Resolution has proved particularly dispensable in the House because the Rules Committee can provide for it to be waived by a simple majority vote (106).

There are 12 Appropriations Subcommittees in both the House and Senate. The individual appropriations bills receive consideration through the normal Congressional Appropriations Committee process as each Subcommittee's bill is drafted; marked up (e.g., amended within the Committee); and reported to the chamber floor for a vote. Many appropriations bills contain certain accounts where the Appropriations Committee can direct funds to individual projects or programs that meet the criteria of that account. This process, known as earmarking, is a subject of some controversy but is an important mechanism to secure Congressional funding for specific programs and priorities, including those advancing the practice of PM&R.

Despite the timeline delineated in the Budget Act, Congress often fails to pass the appropriations bills before the end of the FY. To continue funding for federal programs, Congress must then enact a Continuing Resolution (or series of Continuing Resolutions) to keep the federal government

operating. Typically, these bills extend appropriations at the prior FY level, or even at a reduced level below that of the prior FY, until the next appropriations bill is passed. Congress often achieves passage of the appropriations bills by combining some number of them into a single, large omnibus bill that is easier to pass as it becomes an "all or nothing" proposition (107).

## CRITICAL CURRENT REGULATORY AND LEGISLATIVE ISSUES

At the time of drafting this chapter, a number of major legislative and regulatory issues were under active debate.

### Health Care Reform and Medicare Overhaul

The Obama Administration has announced that health care reform is a high priority and the leadership of the relevant key House and Senate Committees has been immersed in the legislative process of developing a bill. President Obama convened a health reform summit at the White House; Congressional Committee leaders have organized various "stakeholder" meetings to elicit support and educate disparate interest groups; and there is daily press attention on this topic.

As discussed above, the CBO has outlined a number of proposals for reforming the Medicare program, including options to bundle payments for hospital and postacute care and to reduce the update factor for hospitals' inpatient operating payments under Medicare by 1% point (108). This proposal by CBO is extremely significant. Members of Congress and their staff look to the CBO, and to this volume in particular, to find available savings to use for other legislative initiatives. This is especially true in light of the desire by President Barack Obama and key Members of Congress to engage in extensive and costly health care reform. The President's Budget Outline for FY10 calls for "reserve fund of more than \$630 billion over 10 years that will be dedicated toward financing reforms to our health care system" (109). Given the severe current and foreseeable fiscal strains on the government, President Obama has also called for major overhaul of the nation's retiree benefit programs as part of a deficit reduction program (110).

### Definitions of Rehabilitation Providers

CMS continues to conduct various studies designed to review the entire postacute care field, with the stated intention of creating a new measurement system for patients that would be common to all settings, and using that tool to establish a new reimbursement methodology for IRFs, LTCHs, SNFs, and HHAs (111). Medicare is conducting the Post Acute Care Payment Reform Demonstration project (PAC PRD) authorized by the DRA of 2005. Part of that project required the Secretary of the Department of HHS to develop a common patient assessment instrument. The Continuity Assessment Record and Evaluation (CARE) tool (112), developed by CMS' contractor, Research Triangle Institute International (RTI), is, at the time of this writing, the instrument developed

pursuant to the PAC PRD and which may be utilized to establish this “site neutral” payment methodology. The definitions of the various entities that provide rehabilitation services and programs will become even more meaningful under this new proposed reimbursement methodology. In the outpatient venue, CMS is conducting another project, Developing Outpatient Therapy Payment Alternatives, which is also seeking to develop an assessment tool that may be used for a future change in outpatient therapy payments in all settings. RTI is also the CMS contractor on this project. Both of these efforts are comprehensive and represent initial efforts in developing comprehensive data collection tools across the Medicare Part A providers such as IRFs, LTCHs, SNFs and HH and, separately, the vast and more disparate array of outpatient therapy providers paid under Part B of Medicare.

### Medical Necessity Review

A key issue under discussion is the determination of medical necessity by a third party to justify payment for any service provided to a patient. Many commercial insurers, as well as the Medicare program, conduct retrospective audits and reviews of bills and deny payment coverage on the basis of their judgment that the service delivered was not medically necessary and/or could have been provided in a less intensive setting. These reviews by Medicare are conducted by either (a) the FIs (now known as Medicare Administrative Contractors; (b) RAC; or (c) Zone Program Integrity Contractors. CMS has implemented a nationwide version of the RAC Program. Legislation was previously introduced to impose a moratorium on the RAC program, and further legislative action related to RAC contractors and/or medical necessity can be anticipated in the 111th Congress.

### Payment Updates

For the last several years, the President has proposed reducing the IRF market basket update in his annual budget (113). For example, in February 2008, President Bush proposed to freeze IRF's payment update from 2010 to 2011, with a market basket update minus 0.65% after that (113). The budget also set out five procedures for which IRFs and SNFs would receive the same reimbursement (113). The Obama Administration has, as noted above, proposed major reductions in the Medicare and Medicaid programs for FY 2010 in order to fulfill the promises made during the campaign to also propose major health care reforms, but many details have not yet been addressed.

### Methods of Advocacy and Representation

The field of PM&R impacts many stakeholders, including patients, physicians, therapists and other professionals and staff, providers, and families. Given the scope of the issues on the legislative and regulatory horizon, effective advocacy and representation are of more importance than ever before. At the core of the advocacy process is the notion that accurate and informed stakeholder input produces educated and committed Members of Congress, better legislation, and more

effective regulation. In parallel, stakeholders benefit from representation offering expertise in the complexities of the political and legislative processes, as well as the subject area, to function as a necessary intermediary.

Within the field of PM&R, as is common, a number of associations have formed around various concerns and interests within the field. These associations educate and mobilize their members, pool organizational resources, and provide a focal point for advocacy efforts in state capitals and in Washington, DC. The American Medical Rehabilitation Providers Association is the leading national trade association representing over 350 inpatient rehabilitation hospitals, rehabilitation units, outpatient rehabilitation service providers, and several SNFs providing medical rehabilitation services to well over 400,000 people a year. The American Academy of Physical and Rehabilitative Medicine represents physicians dedicated to rehabilitative medical care. National associations representing therapy professionals include the American Physical Therapy Association, American Occupational Therapy Association, and the American Speech-Language-Hearing Association. Patient groups include the American Association of People with Disabilities, the largest national nonprofit cross-disability member organization in the United States.

Given the complexities of the legislative process, professional representation has become an increasingly indispensable element of effective advocacy. Lobbyists working on behalf of PM&R stakeholders, in turn, must often pursue both direct and indirect legislative strategies to succeed in today's advocacy environment.

In executing a direct strategy, the advocate works within the legislative and regulatory policy processes to educate and persuade elected officials and regulators. This requires accurate and credible information about the impact of a policy or proposed policy, presented in a way that the decision maker understands and that is meaningful to him or her both substantively and politically (114). It also requires a detailed knowledge of “how the various institutions work, internally and with each other,” and more generally having “a clear fix on how the government actually works, how the pieces fit together, and how things get done” (114). Direct advocacy involves careful analysis and drafting of legislative proposals; tracking their progress in Congress; arranging meetings on Capitol Hill; working with key Congressional staffers; working with key administrative personnel; and cultivating relationships and alignments.

The most effective advocacy genuinely engages and activates grassroots constituents in the task of educating and communicating with Members of Congress and federal departmental and agency officials. When a Member of Congress understands the impact of a policy—or lack of federal action—on patients, families, and providers within a given community, that Member is more frequently motivated to intervene or undertake Congressional action to be responsive to the constituent and community needs.

An indirect or external communications strategy is often important to demonstrate the extent of grassroots support or

opposition on a given issue. Successful advocacy thus requires building coalitions around common interests and issues and using media and communications techniques to mobilize support and to make it known to key elected officials. National organizations working together with a common agenda and message can enhance effectiveness. Likewise, mixed messages, discord, competing messages, or disparate policy positions within a given field can serve as the quickest way to harm or kill prospects for effective advocacy.

Internet-based technologies have now become an important means to connect people to one another and to their elected representatives and often supplant print and broadcast communications. The challenge for the advocate is to effectively leverage these resources, and that is a challenge that requires lobbyists to be both substantive policy experts and sophisticated communications strategists.

## CONCLUSION

The rule of law is one of the cornerstones of a civilized society. The laws and regulations that impact the care of patients in need of medical rehabilitation are especially complex and important, since rehabilitation functions strongly in the realms of activity and participation, as well as disease and impairment. To successfully practice any discipline within the field of medical rehabilitation, an understanding of the opportunities and restrictions provided by these laws and regulations is necessary. In addition, one part of the responsibility of professionals in the field is advocacy for advancing the cause of persons with a disability, and awareness of rules and regulations that may require amendment or change is essential to that end.

## Ethical Issues in Rehabilitation Medicine

*A 59-year-old man suffered a left hemispheric cerebrovascular accident. Two weeks later, he was admitted to a rehabilitation unit for treatment of deficits resulting from expressive language impairment and right-sided weakness. He did not agree with the self-care, mobility, and speech goals proposed by the rehabilitation team. Rather, he was anxious to return to his home and work. His wife of 30 years was apprehensive about caring for him in light of his level of disability, and urged the team to continue therapy.*

Patients, family members, and practitioners often disagree about the goals, processes, or utility of rehabilitation therapy. Health care practitioners face difficult dilemmas as they attempt to set a course that all parties will endorse. In this patient's case, practitioners were torn between honoring the patient's desire for discharge and respecting the concerns and wishes of his wife. They did not want to treat a patient who failed to provide informed consent, yet they realized that the patient's wife was not prepared to care for him at home. They knew that training would improve his functional abilities and enhance his eventual return home.

Rehabilitation practitioners confront moral quandaries often during the course of practice. A single moral principle—such as that of autonomy or beneficence—may fail to outweigh other principles, yet choices must be made. Practitioners must attempt to reconcile and assign priority to conflicting moral obligations (1). Decisions of a moral nature are distinguishable from those governed by law, technology, religion, or politics. They focus on what is proper rather than on what is possible or legally permissible. Considerations of etiquette, cost, and convenience play an insignificant role in moral decision making.

The terms *moral* and *ethical* are closely related; both stress manners, customs, and character. Cicero apparently used the Latin word *moralis* to translate the Greek *ethikos* (2). Contemporary usage reflects a divergence of meaning, however. *Ethics* refers to theoretical and contemplative descriptions of values. *Morality* describes conduct—that is, whether behaviors are right or wrong. This chapter traces the development of ethical systems in medicine and discusses their application to rehabilitation practice. It describes moral conflicts inherent to issues frequently encountered in clinical rehabilitation practice and recommends approaches to resolve these dilemmas. Policy

issues including resource allocation, health system reforms and costs, and responsibilities of rehabilitation professionals are discussed.

### HISTORICAL DEVELOPMENT

#### Religious Influences

In the 5th century B.C., Hippocrates described scientific, technological, and ethical aspects of medical care (3). The Hippocratic Oath derived from the traditions of a religious sect known as the Pythagoreans. In swearing allegiance to the Oath, a small group of physicians on the Isle of Cos vowed secrecy and loyalty to their teachers and promised to seek the virtues of purity and holiness. Compelled to help patients and forbidden from harming them, physicians alone were qualified to determine how to treat sick patients.

Religious traditions influenced the development of medical ethics through the Middle Ages, when monks dominated medical practice, and beyond (4). Thereafter, Catholics incorporated principles of medical decision making into their moral theology (3). Protestants, too, have examined specific ethical topics in detail and integrated concepts of medical ethics into a larger, systematic theology (3). Orthodox Jews have linked Talmudic and rabbinical teachings to the practice of medicine, with emphasis on the preservation and sanctity of life (3).

#### Secular Influences

During the Age of Enlightenment, the influence of religion on medical morality diminished as secular theories of philosophical reasoning arose. Controversy flourished as scholars studied, debated, and published a range of theories of medical care (3).

Codes of medical practice developed over time in response to medical challenges. In 1789, an epidemic of typhoid created chaos in a British hospital as staff members assumed onerous and unfamiliar responsibilities. As tension heightened and some staff resigned, a retired physician, Thomas Percival, sought to restore calm by designing a code of professional conduct. He instructed physicians to address the needs of individual patients in preference to those of the larger society and to show “tenderness with steadiness and condescension

with authority” since they were to “inspire the minds of their patients with gratitude, respect, and confidence” (5). Percival’s words were repeated in the first professional code of ethics of the American Medical Association published in 1847.

### Recent Developments

Medical ethics evolved relatively little over the ensuing years. But more recently, particularly during the past 40 years, the practice of medicine has evolved dramatically. So, too, has medical ethics. Technological advances have established a scientific basis for medical treatment. Developments in health care and the biological sciences have produced complex and difficult moral dilemmas that transcend discrete professional boundaries.

Callahan describes five factors that give rise to ethical tensions in health care (6). First, technologies such as renal dialysis, organ transplantation, genetic engineering, and embryonal transplantation have expanded our ability to intervene in nature. A strong social commitment to health care coupled with a compelling tendency to apply available technology has made it difficult to restrict the use of technology.

Second, medical resources are costly. When medicine could do little to help people, care tended to be cheap. But now that improved neonatal, emergency, and acute care interventions save many lives, the chronicity and cost of disease have skyrocketed. For more than 40 years, health care costs have risen substantially faster than personal income or the overall economy (7). At \$2 trillion annually, health care expenditures now exceed one sixth of the American economy (8).

Callahan cites an expanded role of the public as a third factor prompting recognition of ethical issues (6). The solitary and secretive aura of Hippocratic medicine has been supplanted by health care that is conducted in an increasingly public arena. More than 80% of Americans die in hospitals. Taxpayers fund health care entitlement programs and support medical research. Research on human subjects is regulated by federally mandated Institutional Review Boards. Legislation is in place to protect patients and assure their privacy.

The language of rights has evolved as well. Support for individual rights in American society and enhanced respect for the rights of racial minorities, women, and disabled persons have directed attention to patients’ rights. In the medical context, respect for self-determination and personal dignity requires recognition that patients have a right to make their own decisions (3).

Finally, Callahan cites increasing concern about quality of life, since many lives are now preserved and extended by medical interventions. We may wonder, however, what kind of life some survivors will lead (9). At times, the burdens of cure appear to outweigh its benefits (10).

Dramatic change has spread throughout the health care insurance industry in recent years. Mechanisms of reimbursement for health care have shifted due to the emergence of managed care and other for-profit systems. Expectations concerning the relationships and roles of payers, practitioners, and consumers have been profoundly altered.

### What About Rehabilitation?

Until the recent past, little formal attention was directed to ethical aspects of rehabilitative care. A number of explanations exist (11). Still a relatively young field, rehabilitation medicine has sought to acquire recognition and acceptance by the medical community (12). Its chronic care dilemmas may seem to lack the drama of life-and-death decisions. Often patients are treated over an extended period of time by a broad range of practitioners, none of whom possesses clear responsibility for addressing ethical issues.

Recognition of moral dilemmas inherent to chronic care has increased interest in ethical aspects of rehabilitation. Questions have been raised about duties of professionals, dynamics of professional-patient relationships, roles and expectations of family members, and goals of care (11,13–29). A discussion of fundamental ethical principles furnishes a conceptual framework to study issues relevant to rehabilitation medicine.

### Ethical Principles: Beneficence, Autonomy, and Justice

The term *beneficence* connotes kindness, charity, and the doing of good; it refers to a moral obligation to help other people, refrain from harming them, and attempt to balance benefits with harms. In the health care setting, beneficence entails an obligation to promote the health and well-being of patients and to prevent disease, injury, pain, and suffering (2).

Whether beneficence can be assured is uncertain when patients’ values conflict with traditional medical values of healing and care. Differences of opinion among patients, family members, and professionals about the best interests of patients or criteria for a good quality of life are not easily resolved. Discrepant interests may be difficult to balance within a moral framework. Beauchamp and McCullough suggest that “beneficence includes the obligation to balance benefits against harms, benefits against alternative benefits, and harms against alternative harms” (4).

The principle of *autonomy* is grounded in the notion of respect for the values and beliefs of other people. Americans are entitled to privacy and to make decisions about their lives. They are perceived as possessing a right to self-determination that ensures freedom to make personal choices and resist the intervention of others. Within the context of health care, autonomy underlies the medical doctrine of informed consent. There is an obligation to inform patients accurately about their diagnoses and treatment alternatives, as well as to seek their permission before instituting treatment. Decisions are respected, even if they appear to be unwise (2,4).

Many authors describe tension between the principle of beneficence, which requires acting in a patient’s best interests, and that of autonomy, which entails respecting patient choices (4,30). Balancing the two principles is a perpetual struggle for health care givers who consider certain decisions of patients to be harmful. It is not clear how to view patient behavior when patient choices seem at odds with information presented to them. To Englehardt, “the moral obligation to

respect persons will often constrain physicians to acquiesce in patients' choices—choices that most likely will lead to the loss of important goods" (30). In everyday practice, health care givers may be tempted to act paternalistically by restricting patient freedom to make autonomous choices if those choices appear to compromise the patient's best interests.

The principle of *justice* concerns questions of what is due to whom and how to distribute the burdens and benefits of living in a society. An egalitarian model of distribution obliges society to provide all its members with a fair share of health care resources and to treat people equitably. However, scarcity of resources or competition for them can create conflict (2). Is it fairer for people to share social goods equally, or for those who have less to be given more?

Americans have yet to define the basic medical services that will be provided for all citizens. For example, despite the fact that sexually transmitted diseases are relatively common and may present public health hazards, some people receive neither prevention nor treatment efforts. But other treatments, such as organ transplants or elective cosmetic surgery, appear to be readily available to some patients. Entitlement programs in certain states pay for procedures not funded in others. Emergency treatments may be generally available, but aftercare and rehabilitation to improve the lives saved may not be funded adequately. Millions of Americans, many of whom work, do not qualify for publicly funded insurance programs, yet cannot afford to buy private health care insurance. Even for those who have insurance, reimbursement plans may provide vastly differing levels of coverage.

Concern for individual dignity and choice has overshadowed a holistic view of society's needs. Callahan ponders what kind of medicine is needed by a society which must address other needs, including education, housing, welfare, and culture (9). Determining how much health care to support spurs us to reflect on how we want to live within our larger society. Fundamental questions of meaning are not easy to answer. In contrast to other developed nations which may possess a strong orientation to community, Americans have lagged in developing and implementing a sound health care delivery system based on a just social policy.

## CLINICAL PRACTICE ISSUES

Acute care physicians attempt to save lives, relieve symptoms, reverse the course of pathologic processes, and discharge medically stable patients. Unlike acute care medicine, rehabilitation does not center on a sick patient whom treatment is expected to cure. Rather, rehabilitation practitioners treat dysfunctions that are chronic, often irreversible, and rarely curable. Residual disability may well persist throughout a person's life.

Medical rehabilitative care addresses impairment caused by pathologic processes that include disease, accident, and congenital abnormality. Disabled persons experience restricted ability to perform certain functions. When unable to execute activities important to role fulfillment, a person is said

to be handicapped (31). Rehabilitation therapy attempts to ameliorate handicap by restoring skills and capabilities through functional retraining and environmental adaptation. Many professionals—including, but not limited to, physicians, nurses, psychologists, social workers, and educators, as well as physical, speech, occupational, recreational, and vocational therapists—contribute to this effort. They must reach beyond pathology and physiologic dysfunction to understand the unique familial, social, vocational, psychological, and financial dimensions of patients. Successful rehabilitation requires attention not only to medical but to nonmedical factors ranging from skin tolerance to household layout and availability of caregivers.

The need for a team of rehabilitation professionals and family members to engage in each patient's treatment leads to complex relationships that may be portrayed by three points of a triangle representing patient; family, generally including several people; and health care team, including practitioners of multiple disciplines. Those at each point share concerns with others but harbor unique considerations as well. Competing rights and obligations of patients, family members, and practitioners, and blurred responsibilities and loyalties can cause confusion or conflict.

Following the seminal description of ethical issues in rehabilitation medicine in the Hastings Center Report in 1987, Kirschner studied ethical issues of greatest concern to rehabilitation clinicians (17,32). Practicing clinicians were asked to describe ethical conflicts encountered in daily practice. A broad range of clinicians listed four primary issues: reimbursement and allocation of scarce resources; determination of rehabilitation goals; compromised decision-making capacity in patients; and concerns about confidentiality (32). They considered conflicts among the treatment team especially troubling. Practitioners expressed unease about balancing their obligations to payers with their roles as patient advocates. How to ensure justice in treatment decisions worried them.

In another study, registered nurses, many of whom held management positions, reported concern about misallocation of medical resources—including both overtreatment and suboptimal treatment of patients (33). They questioned how to assure an optimal balance of providing good and avoiding harm while respecting patient autonomy. Ethical issues identified in similar surveys (Table 20-1) are discussed in this chapter within the context of clinical and policy dilemmas inherent to rehabilitation care.

### Selection of Patients

Provision of medical care in the United States does not necessarily reflect need for it; in 2007, more than 47 million Americans lacked health insurance, and over one third of the population under the age of 65 was uninsured at some point in that year or in 2006 (34). Even for patients who are insured by Medicare, studies have shown that race, income level, and geography affect the care received (35). Many patients may not be entitled to reimbursement for rehabilitation, nor is rehabilitative care guaranteed for those whose lives have been saved by acute care interventions.

**TABLE 20.1 Clinical Practice to Rehabilitation Care**

Clinical Practice Issues	Policy Issues
1. Selection of patients	1. Allocation of resources
2. Goal setting for patients	2. Medical insurance and implications for rehabilitation
3. Patient-practitioner relationships	3. Professional responsibilities
4. Professional and team issues	
5. Duties and rights of family members	
6. Quality of life and termination of treatment	

Rehabilitation practitioners screen potential patients before selecting those who will receive treatment. Providers recognize that not all patients will benefit from rehabilitation therapy, since some are too ill to participate in therapy or have impairments that are difficult to rehabilitate, while others have relatively insignificant functional impairment (36). Assessment of prospective patients requires practitioners to review information derived from hospital records and consult with referring and other treating professionals. They may also examine patients or interview family members.

Because treatment requires patients to solve problems by applying new approaches to their functional needs, their ability to learn and retain information is considered crucial to successful rehabilitation. A person's age and predicted course of recovery also influence a decision to initiate care. Those patients who are anticipated to make significant progress are usually viewed as good candidates for rehabilitation despite severe dysfunction.

Practitioners explore nonmedical parameters in admission decisions. Particular attention is directed to whether family members are physically and emotionally available to help patients, because strong social support systems correlate with positive patient outcomes (37). Financial capacity is a powerful determinant of access to services, since gains made during treatment are more likely to be retained if financial resources are available for further services or equipment as needed.

Features of the rehabilitation unit itself influence selection of patients. Some units specialize in treatment of specific disorders or impairments. Others emphasize training patients for work or independent living. Fluctuating bed availability or staffing patterns may affect selection such that surplus program capacity at a given time may prompt admission of patients who might otherwise be rejected (16).

### Values

Although practitioners are guided in the selection process by a patient's potential to benefit, some professionals may neglect evidence-based information regarding rehabilitation prognosis. Ability to pay and the burden of care that staff are likely to

experience also influence decisions, yet the fact that admission criteria are not publicly disclosed not only confers significant flexibility on decision makers but creates a potential for injustice as a result of bias or subjectivity. A lack of training with respect to moral dilemmas may cause practitioners to make judgments that reflect their personal belief systems and values (16). Decisions may also be influenced by perceptions that society desires to save money in its care for disabled persons, or by practitioner bias about the likelihood of good rehabilitation outcomes in older patients (17). Decisions may be made without sufficient understanding of the body of evidence-based information regarding rehabilitation prognosis.

Dilemmas in selection abound. Who should be selected: a patient with considerable need but a relatively poor prognosis, or one with lesser need and disability, but the likelihood of a better outcome? A young person who will apply his or her training throughout a lengthy life span, or an older person with few remaining years despite his contributions to society over a lifetime? How much treatment should be available to patients who bear responsibility for their disability, or for those who have been noncompliant with past treatment?

Our current approach to patient selection seems to favor those already well off. Englehardt describes the impact of lotteries: a "natural lottery" of one's talents and abilities, diseases and illnesses; and a "social lottery" that includes educational and work status, financial and insurance profiles, and social attractiveness (38). "Winners" can navigate complicated medical systems to gain assistance coping with disease, but "losers" may be uninformed about even the availability of services and resources. Patients disadvantaged by socioeconomic factors may experience restricted access to rehabilitation, but absent an explanation for this rejection, they are unlikely to challenge selection decisions effectively.

### Recommendations

Potential for injustice inheres to a system that fails to provide clear criteria or standards for those who make difficult selection determinations. Although screening is necessary to assure that patients are medically stable and to demonstrate that they have remediable functional disabilities, the screening process has significant shortcomings. Practitioners should standardize selection guidelines and formulate them in writing. Reasons for rejecting patients, and a commitment to reevaluating those patients in the future, should be assured. Otherwise, a single decision made relatively early in the course of disease may preclude rehabilitative care entirely. A mechanism for patient appeals could provide valuable checks and balances to the selection process.

### Goal Setting for Individual Patients

In order to develop patient treatment plans, staff members discuss the requirements of the postdischarge environment with patients and their family members. Initial treatment goals are outlined, reviewed, and adjusted during the course of therapy to ensure the relevance and feasibility of patient goals over time.

Authors who have addressed goal setting during patient care include Trieschman, who emphasizes the importance of consulting with patients and family members to cast and refine goals (22,24,25,39–42). She cautions caregivers to refrain from imposing goals on patients who may reject them in the long run anyway and stresses the importance of assuring transfer of skills from the rehabilitation setting to the home environment (42). Becker et al. emphasize the need to promote close interaction among family and staff members and to assure that the full team resolves discrepancies among treatment goals (39).

### Problems of Current Practice

Although rehabilitation practitioners encourage patients to participate in designing their treatment program, this may be difficult for some patients. On admission to rehabilitation, many patients are exhausted by pain, weakness, fatigue, depression, or anxiety. Few come to terms with new or exacerbated disability and the demands of their condition absent real-life and home experiences that could illuminate their post-discharge needs (25,43). They may know little about what can be achieved from rehabilitation. The rehabilitation unit itself may be unsettling. Expectation to socialize with strangers who may have visible scars and dysfunction at the very time that visits from friends and family are restricted by a demanding therapeutic schedule may cause patients to feel cut off from all that is familiar.

### Values

People have different interpretations of data about probabilities and outcomes. One's approach to information regarding risks and benefits, pain, cost, health, and disability is influenced by his or her personal values. It is not uncommon for patients, family members, health care teams, and insurers to advocate for discrepant or even mutually exclusive goals. Patients are likely to want to make their own decisions; they know best what is personally meaningful and how exhausted or disheartened they feel. At the same time, they may feel indebted to family members who want to pursue different goals. Relatives may believe that their opinions should take priority since they will be serving as caregivers. Practitioners' experiences with disability may incline them to usurp decision-making power rather than to accept patient or family choices that appear likely to expend time, money, or effort unnecessarily. Tensions abound (25–27).

### Recommendations

The principle of autonomy holds self-determination paramount regardless of whether patients make ill-advised choices. We know that patient autonomy can be compromised by limited knowledge of medicine. But the technical expertise possessed by practitioners does not imply moral authority. Professionals should refrain from imposing their personal values on patients who generally know best what makes sense for themselves. Experience demonstrates that in an unrestricted environment, former patients may refuse tasks that require extensive time, patience, or concentration. They may discard unattractive or

cumbersome equipment and ignore recommendations for self-care and home exercise programs. Transportation, social networks, or finances may be insufficient to support interventions made in the rehabilitation setting (25).

Practitioners may not appreciate the potency of their recommendations for patients who have experienced profound, often abrupt, loss of physical ability. Patients require education about the costs, risks, and effectiveness of treatment options, and benefit from an opportunity to explore fully the medical and functional ramifications of alternative treatment approaches (44). Clinicians should communicate the values, ethical norms, and institutional priorities that underlie their recommendations. Tauber believes that only sustained, deliberate efforts to elucidate values held by all interested parties and to delineate major conflicts among those values help to resolve the moral tensions that impact care of disabled persons (45).

### Patient-Practitioner Relationships

Relationships between rehabilitation patients and care providers are likely to be of long duration, in contrast to some acute care relationships (15). The nature of the moral rules and principles that determine exchange of information and provision of services in extended health care relationships bears exploration.

### Contractual Model

American laws and customs have evolved over time with respect to patient rights. An increasingly egalitarian relationship between patients and practitioners has displaced paternalism (17). A “contractual” model of care requires practitioners to tell patients the truth about their circumstances and to present options in an accurate and balanced manner. A professional duty to act beneficently toward patients is constrained by respect for patient autonomy. Physicians supply the medical care desired by autonomous people who make informed decisions about that care. Respect for confidentiality and patient privacy is deemed essential to the development of trusting and egalitarian relationships between patients and physicians.

Caplan describes factors that compromise the relevance of a contractual model to rehabilitation (15). Relationships in rehabilitation are multifaceted rather than restricted to a single practitioner and patient. Patients have multiple health care providers, and family members, too, often assume an integral role in treatment. People who have experienced profound impairment need time to adjust to the reality of disability. Many are anguished by their functional losses. Facing an uncertain future and possessing little knowledge of ways that disability will impact their life choices, patients may feel unprepared to make important decisions. Similarly, family members are likely to be unfamiliar with issues that arise in the context of their loved ones' impairments.

### Competency and Recommendations

Caplan describes the complex and evolving nature of relationships among patients and their rehabilitation providers.

He argues that an effective and proper role of physicians in medical decision making may entail more guidance on the part of professionals than a model that specifies the physician as a provider of information to an autonomous patient (15). He notes that the competence of patients during the earliest phases of rehabilitation treatment may be questionable, and contends that rehabilitation professionals are justified in overriding the autonomous wishes of patients at the outset of treatment (17,22,26,27). If patients have not yet adapted to impairment or come to understand their future possibilities, Caplan suggests that practitioners are justified in using persuasion to encourage even reluctant patients to participate in early rehabilitation. He recognizes that this approach tolerates more beneficence on the part of providers than customary in contemporary medicine, but suggests that over the long run, it restores patient identity, capacity to cope, and autonomy (15). Caplan characterizes this as an “educational model” of care. He underscores the importance of earning the understanding and cooperation of patients at the same time that practitioners seek to understand patients’ values and preferences as fully as possible.

Periodic assessment of patient capacities to make autonomous choices is essential. Practitioners must focus on restoring autonomy quickly so that patients will resume decision making as they adjust to the consequences of impairment. An independent committee could be charged with assuring that patient autonomy is enhanced as soon as possible during treatment. Paternalism would be considered appropriate only as a bridge to restoring autonomy to patients, with practitioners recognizing that beneficence, however well intended, may compromise a patient’s best interests over time (17).

Assessment of competency in patients with neuropsychological dysfunction requires presenting information in modalities and formats that patients are able to process. Simple tests such as the mini-mental status exam may be inadequate to discern patient capacity. More comprehensive evaluation, including determining specific competencies in appropriate contexts over time, may be needed to understand patient decision-making capacity. In the event that patients and caregivers disagree on a course of treatment, the values underlying those disagreements should be discerned and discussed thoughtfully, rather than providers assuming that a patient is incompetent. Competent patients understand potential benefits, risks, and consequences of treatment options and can communicate their decisions (44,46,47).

### Professional and Team Issues

Rehabilitation treatment is delivered by a multidisciplinary group of professionals who work together as a team. Amelioration of patients’ functional deficits, psychosocial challenges, and vocational needs requires rehabilitation teams to provide coordinated and comprehensive treatment generally not offered by individual caregivers who work independently. Experienced teams have demonstrated the ability to provide efficient, organized services (19,22).

### Moral Problems of Teams

Patients and family members may be relatively unaccustomed to working intimately with so many practitioners in the health care setting. Distinguishing the responsibilities and lines of authority among team members may be challenging. Clarifying what each professional expects and needs to know is not easy for many patients. Acting consistently while working with a wide variety of professionals can be daunting for them as well.

Members of a rehabilitation team should recognize the vulnerability of patients to team pressure, no matter how subtle. Patients who are exhausted, frightened, or confused may be intimidated by professionals. Purtilo suggests that patients may feel compelled to follow recommendations with which they do not agree when outnumbered by the team (19). Sometimes team members need to decide how to treat patient “secrets” or how to reconcile conflicting information gathered from patients and relatives.

Practitioners serve as teachers and guides to enhance patient function and assist adjustment to disability. Addressing the needs of many patients simultaneously requires the team to balance the conflicting interests of multiple patients. Institutional policies about patient schedules, smoking, or electronic devices, for example, may clash with the wishes of particular patients. The team must balance the interests of individuals with those of the collective and the guidelines of the institution (17).

Controversy about authority and responsibility can arise among team members as they recommend diverse and perhaps conflicting goals for patients or disagree about setting priorities among consensus goals. Certain team members may wish to work with patients in ways that conflict with those of their colleagues (48). A team in which authority is distributed may not have agreed on a method to resolve dissension. In addition, the fact that team members share lengthy and strenuous work hours may impose a sense of loyalty that makes some members uncomfortable questioning others.

### Recommendations

Purtilo suggests that teams explore and clarify personal and shared values in order to develop a “common moral language” to frame ethical decisions (19). Team members should be trained about and practice effective team dynamics, and should work within a framework of administrative guidelines that promote airing and resolution of conflicts (17,32). Accountable to the entire team for their actions, each member should be encouraged to raise questions about professional behaviors that seem to compromise patient interests. Team members must assure their accessibility to patients and families and strive to avoid intimidating them inadvertently. Even patients or families who are difficult to manage must be treated respectfully.

Professionals should explain to patients and their relatives how teams share responsibility and designate authority (17). Lines of communication should be clarified to alleviate patient uncertainty. Families should know what to expect in terms of decision making. Practitioners should protect patient privacy

and confidentiality to the extent possible, while emphasizing to patients and relatives the need to share relevant information among those involved in a patient's care. Teams should strive to resolve the conflicts that inevitably arise among patients, family members, and professionals. They should seek advice and support from other professionals when such insight can advance rational decision making (47). Ethics committees can be asked to provide a neutral forum for discussion and mediation.

### **Duties and Rights of Family Members**

Family members frequently assume a vitally important role in the care of disabled relatives. The interest and commitment of relatives may determine whether a patient is admitted for rehabilitation. During treatment, family members are expected to meet with the team to learn caregiving skills, revise treatment goals, and establish postdischarge arrangements.

### **Obligations**

There is an expectation on the part of society that relatives will assist one another when needs arise. Family or family-like relationships are considered uniquely extensive and interconnected (17). Family members often undertake caretaking duties with the understanding that they are able to provide special emotional support and affection as well as the physical care that patients require (14).

The need for family caretaking has increased as the extent and cost of professional care have risen (49). Some rehabilitative care has shifted to home settings. Early discharge to home is thought to enhance patient autonomy while enabling patients to test their skills and the feasibility of their goals in a real-life setting. Outpatient or home settings are preferred by many patients and are less expensive than inpatient facilities.

A randomized, controlled trial of stroke patients with moderately severe disability contrasted routine hospital rehabilitation and early discharge with rehabilitation care provided at home. Patients in the latter group showed better recovery of activities of daily living, ambulation, motor capacity, manual dexterity, socialization, and satisfaction. They required half the resources of the hospitalized group and experienced no difficulties in the use of home help. A negative impact on family caregivers was not noted (50).

Callahan has observed that many families discover that providing care to their disabled members is mutually satisfying and rewarding (14). Caretakers develop and hone skills and resources to adapt effectively to shifting demands. They may take pride in their ability to identify patient needs and to provide care sensitively and with compassion. Some family members are exceptionally responsive to a relative's situation and thus offer optimal care.

Other families experience difficulties, however. Unresolved tensions among patients and caregivers may interfere with satisfactory relationships. The demands of caring for a disabled person may exceed the capacities of some family members. Strain may result from limited financial resources or inadequate physical supports. Relatives may feel angry, sad, or depressed

about the condition of their loved one. They may question whether they are prepared to cope over long years with the circumstances of a severely disabled person or one who has an uncertain prognosis. Facing an unanticipated situation that they have not chosen, their personal happiness or autonomy may feel threatened.

### **Limits of Duty**

There is no simple formula to determine what family members ought to be expected to give patients, or to identify the limits of duty. Some relatives may gladly dedicate the remainder of their days to caregiving, whereas others may view this as unjustified self-sacrifice (14). Family commitments are complicated by the fact that families today are smaller and more dispersed than in the past, making it difficult to share caregiving tasks among several relatives. Women may feel a special responsibility to become caretakers, but employment often restricts their availability to do so. Some families are not physically able to provide adequate care despite wishing to do so, whereas the financial or emotional resources of others are too meager. Some relatives are unwilling to relinquish personal plans, hopes, or dreams even if they are best qualified to address patient needs and vulnerabilities (14). Health care providers rarely have sufficient understanding about the lives and intimate relationships of specific patients and family members to know what to advise in difficult situations.

### **Recommendations**

Practitioners may be uncertain about the amount of persuasion that is justified in an attempt to encourage potential caregivers to commit themselves to patients. When patient needs are minimal and family members poised to sacrifice relatively little, the patient's best interests may well entail encouraging relatives to fulfill family obligations. In circumstances of severe disability in which significant sacrifice will be required, however, strong persuasion does not appear justified. Callahan points out that our society neither rewards nor honors people who transcend their own needs to care for others. Such people are, in fact, more likely to meet with social isolation than with commendation and should not be expected to act as heroes (14).

Society has yet to develop mechanisms to reimburse the financial and psychological services that could minimize the burden on caregivers. It is critical that family members are furnished with tools to sustain them, including daycare centers, respite care, counseling, self-help groups, and adequate physical facilities (49). Only then can society expect any but the most extraordinary people to embrace an opportunity to care for a seriously disabled relative.

### **Quality of Life and Termination of Treatment**

Many factors contribute to decisions to terminate treatment in the rehabilitation setting (17). Patients undergoing rehabilitation care are expected to make steady and measurable progress toward attaining their goals. When progress slows significantly or patients appear to have reached a plateau in

degree of improvement, members of the treatment team may doubt whether continued therapy is justified. Such questions about efficacy of treatment are typically raised first by professionals rather than family. At times, patients and their relatives seek goals that professionals no longer consider realistic or important. At other times, clinicians may be concerned that patients who are scheduled for discharge have received insufficient treatment (33).

### Whose Values?

Moral values of team members influence decisions to terminate treatment. Practitioners assess somewhat nebulous concepts, such as “benefit,” “productivity,” “functional improvement,” and “integration into society” to delineate end points of treatment (39–41,51). Their subjective judgments about the capacity of patients to cope with impairment outside the rehabilitation setting and the validity of family members’ requests for services and equipment affect their appraisals. Practitioner perceptions about acceptable levels of function do likewise, even though their personal values may differ substantially from those of patients (17). Not uncommonly, insurance providers determine the length and timing of treatment, which may not reflect a time frame that patients or practitioners consider reasonable. It is time-consuming for practitioners to advocate for public policies to assure adequate reimbursement by insurance plans for evidence-based rehabilitation therapy.

Our society lacks a common context that relates ambiguous concepts of health, function, and quality of life to cherished personal values such as autonomy and independence. Medical practitioners do not have the final word on quality of life, nor are their theoretical views—particularly if unexamined—necessarily more insightful than those of others.

Research about the quality of life of persons with disability indicates that adversity does not necessarily cause a person to appraise his quality of life negatively (52). In fact, persons who adapt to disability may be wholly satisfied with the meaningfulness of life (53). However, gaps between one’s activities, aspirations, and accomplishments may impair quality of life to the extent that significance is attached to those unattained wishes (54). To assure thoughtful decisions about terminating treatment, practitioners must understand the critical importance of patients’ values in impacting patient assessments of elements that make their lives satisfying.

The progress of some patients during rehabilitation may be examined sooner than that of others. Patients who are considered noncompliant, uncooperative, or poorly motivated may be so difficult to manage that the team discusses discharge relatively early in the course of treatment. Other patients have limited insurance coverage. Professionals may feel pressured to use scarce institutional resources for new patients, and thus decide to wean care from longer-term patients. A patient’s home setting and his anticipated need for assistance at discharge also affect the timing of a decision to curtail care.

In recent years, it has become increasingly common for patients to begin rehabilitation care before they are able to participate fully in training. Because some patients may not

be eligible for readmission following a temporary discharge, practitioners may be reluctant to interrupt treatment early. At other times, onset of medical complications results in transfer to acute care, regardless of progress made in rehabilitation. Whether to readmit patients for additional treatment can be a source of disagreement among both patients and professionals.

### Recommendations

Even wise and morally sensitive caregivers feel challenged to allocate care wisely among patients. Sometimes, rehabilitation teams fail to explain the criteria that influence their decision to end treatment. At other times, patients and relatives may not appreciate the significance of the factors assessed. Surely, patients and their families have a right to know the parameters used to evaluate patient progress and the guidelines that determine whether treatment will be continued. Practitioners have a duty to document patient milestones in order to assure that objective data underlie decisions to stop care. Engaging patients and relatives in team discussions about termination of care is essential if their desires are to be honored (17).

## POLICY ISSUES

### Allocation of Resources

Over 125 million Americans live with chronic illness, disability, or functional limitations (55). Babies who would have died from complications of prematurity or congenital abnormality only a few years ago survive, often with significant disability. Many severely injured people overcome life-threatening conditions. Rapid medical triage and substantial technological advance enable victims of severe war wounds to survive. Americans today live considerably longer than their ancestors; by 2040, 23% of the population will be older than 65 years (56). Population growth, extended life span, and successful acute care interventions have rendered chronic disease increasingly prevalent. Persons with chronic disease frequently benefit from rehabilitation services to enhance their functional skills at work, school, or in the home (49).

### Costs of Health Care and Limitations of Access

Costs of health care have increased annually since the 1980s. In 1950, approximately 5% of gross national product (GNP) was spent on health care; by 1998, health expenditures were 15% of the GNP, by far the highest level in the world and nearly double that of the nearest competitor nation (57,58). Today’s health spending represents 16% of GNP (56). Even middle-income Americans worry that they may be excluded from necessary health care services because of inability to pay (59).

Our national appetite for medical care increases. Costs are driven by hospital-based services, complex technology, fee-for-service reimbursement plans, litigation concerns, and treatment of patients near the end of life (56). Treatment of severe injury is costly as well; some who survive trauma to the brain or spinal cord require care costing hundreds of thousands of dollars.

High costs of care and generalized economic tightening have restricted access to care. The Census Bureau's March 2000 Population Survey indicated that more than a third of poor families and a quarter of near-poor families (those with incomes between 100% and 199% of the poverty level) lacked health care coverage. Categorical restrictions and ceilings on income eligibility for Medicaid exclude many employed low-income people; 72% of uninsured persons live in families with at least one full-time worker. Impoverished adults are more likely than children to be uninsured (43% and 26%, respectively), despite the fact that 71% of those who are uninsured have completed high school, and more than a third have had some college education (60).

Studies show that although less healthy people are more likely than those who are healthy to qualify for public coverage, they are less likely to be insured. Minorities are uninsured in higher numbers than the white population. People who live in inner city or rural areas often have restricted access to care. Those who lack care have worse health than those who receive services, even controlling for factors such as increased stress and poor hygiene (61).

Churchill comments that, despite a sense of moral repugnance, Americans do ration health care according to the ability to pay (56). Many uninsured people forego preventive care and basic services such as eyeglasses, hearing aids, and routine dental care. Even desperately needed care is typically sporadic for those without financial resources. The Commonwealth Fund conducted a health survey of 12,000 adults in seven developed countries (Australia, Canada, Germany, the Netherlands, New Zealand, the United Kingdom, and the United States). Americans were most likely to complain of restricted access to care; 37% of those surveyed reported skipping doctor visits, tests, and prescriptions in the preceding year due to cost (62).

Interventions designed to extend life often overshadow those that enhance its quality. The heroism and drama of rescue medicine prevail over seemingly mundane preventive and primary care interventions. Our fragmented, uncoordinated system of private health insurance and publicly funded entitlement programs fails to address the medical needs of many, especially those who have chronic disease. Allocation decisions are made absent a larger context that would help to identify and weigh priorities (9).

### Principle of Justice

A just society does not allocate health care to favor those who are insured, wealthy, and white. A morally acceptable health care system must honor principles of equity and justice. We respect a community that offers mutual and reciprocal assistance to its members and honors its social obligations to care for those who are sick without discriminating among individuals. After all, no one is immune to unexpected disease or calamity—misfortune can, in fact, strengthen human bonds of mutual affection (56).

But what services should be offered in a society that cannot afford everything? Principles of utility would direct us to select services that provide the greatest good for the greatest

number of people (2). Principles of justice imply that services should be based on need. Yet, assessment of need may be subjective, biased by highly individualistic desires, hopes, and preferences (9).

In an environment of finite resources, limits on health care should derive from generic guidelines that apply to common conditions. Personalized appeals for specialized services should be discouraged (56). Access to basic and primary care improves health outcome; use of more specialized care should depend on evidence regarding its effectiveness and an understanding of the efficiency with which it can be provided. Costly care of marginal benefit should be replaced by treatments that improve quality of life.

Some health care planners have concluded that poorly distributed medical services may compromise not only the health of those persons who have inadequate access to care but also those who receive excessive services. A 2004 federal study showed no differences in health outcomes across America, regardless of substantial disparities in health care spending among regions. For example, per capita spending in Utah was just 59% of that in Massachusetts, yet population health ratings were similar (63).

In a comparative study of patients conducted in Minneapolis, Miami, Portland, Oregon, and Orange County, California, neither life expectancy nor quality of life in the last 6 months of life was improved by spending more on health care (64). Expenditures in Miami far exceeded those in Minneapolis, yet medical outcomes were similar. During the 6 months prior to death, Medicare costs in Miami were double that of Minneapolis. Miami patients visited medical specialists six times more frequently than those in Minneapolis, spent twice as much time in the hospital, and were admitted to intensive care units more than twice as often. Lifetime spending for a typical 65-year-old in Miami was \$50,000 more than in Minneapolis. But no difference in outcomes was noted. The Congressional Budget Office estimates that less than half of all medical care in the United States is supported by sound evidence of its effectiveness (7). In fact, hospitalized patients may actually do worse than those who receive less treatment and experience fewer infections and other complications of treatment.

### Recent Evolution of Medical Insurance and Implications for Rehabilitation

Despite benefiting from the most advanced medical technology in the world, Americans worry that such care may one day exceed their economic reach. The last major change in federal health care policy was the 1965 Medicare Act. In 1971, President Richard Nixon tried to forestall the ensuing national interest in single payer health insurance by proposing federal mandates for employer coverage and a Medicaid-like program available to those who were otherwise not insured with income-based sliding scale premiums. Although federal legislation with these provisions was never passed, increases in health costs over the next two decades drove states including Massachusetts, Vermont, Oregon, Minnesota, and Tennessee

to implement mandates for coverage. Such programs, however, proved costly and troublesome to implement as legislators repeatedly failed to enforce the mandates or to finance new coverage for the poor. Even those persons who faced fines were unable to purchase health insurance if they did not receive subsidies. The number of uninsured Americans continued to rise (65).

By the early 1990s, concern about inadequate health care coverage prompted President Bill Clinton to appoint a task force to draft reform measures ensuring universal and affordable health care. Although those reform efforts failed, the focus on health care costs propelled changes in systems of reimbursement, including managed care, that were intended to control medical costs.

Rates and duration of hospitalization decreased thereafter, but overall medical costs continue to grow. No reform effort included real cost controls (56,61).

Reliance in America on private health insurance continues to make universal coverage unaffordable, as a relentless rise in costs drives up insurance premiums. A 2008 report of the Commonwealth Fund indicated that although the United States spends more than twice as much per capita as other industrialized nations on health care, it ranks last in preventable mortality. Many developed countries, by comparison, have more centralized health systems and public insurance. Even in countries with private insurance such as Germany and Switzerland, more efficient insurance administration reduces costs substantially (66). An estimated \$350 billion, or nearly 30% of health care expenditures, is spent annually on American medical bureaucracy (66).

The 2008 Commonwealth Fund report indicates that 75 million Americans are believed to lack any or adequate health insurance. The economic expansion of 2000 to 2007 created no increase in real household income. As premiums have increased faster than wages and inflation, more people have sought insurance from public programs such as Medicaid and the State Children's Health Insurance Program. The number of people covered by private insurance or employers continues to decline (66,67). A national survey of employers revealed skepticism regarding employer mandates to fund insurance for uninsured persons through employer health care plans and payroll taxes. A small business lobbying group has announced opposition to Medicare-style single payer financing (68). And, despite substantial public pressure during the fall of 2007, Congress was unable to override President Bush's veto of legislation to expand the State Children's Health Insurance Program from 6.6 million children to more than 10 million uninsured children.

One notable exception to the failure to provide health insurance to all citizens is a program currently under way in Massachusetts. In 2006, the Republican governor and Democratic-controlled legislature enacted far-reaching health insurance reform. All residents must subscribe to health insurance or suffer a tax penalty; employers must offer coverage or pay a small assessment if they do not do so. An expanded state/federal Medicaid program is available to low-income

individuals, who otherwise receive subsidies to help purchase private insurance offered at substantially lower rates than in the past. By mid-2008, two thirds of those who lacked health insurance at the outset of the program were covered, including 40% of whom now had private policies without using government subsidies. The cost of the program per person, shared between the state and redirected federal funds, has been less than anticipated, although unexpectedly rapid enrollment has increased the total budget for subsidized care (69).

Concerns about access, cost, and quality of health care are once again receiving national political attention. Throughout the 2008 presidential campaign, the public voiced strong support for guaranteed health care after presidential hopeful John Edwards proposed a plan for universal health insurance in February 2007. Both major political parties responded to public interest.

Some politicians recommended modeling health care reform on new public policies, and others advocated expanding the Federal Employees' Health Benefits Program, which currently provides health care to 8 million federal employees through an array of private and public insurance plans.

Both nominees for president in 2008 proposed health insurance plans. Democratic nominee Barack Obama emphasized mandates for employers to provide health coverage for employees or pay a tax and proposed subsidies and tax credits for small businesses and individuals, regulating the insurance industry and enhancing competition among payers. Republican nominee John McCain proposed a market-based plan predicated on individuals purchasing insurance with universally available tax credits or refunds. The existing employer tax advantage for offering health insurance would be cancelled, calling into question whether employers would continue to offer such plans (70,71).

Election-year interest in health care access, quality, and costs continues. A panel of experts on medicine, academia, business, insurance, and politics was convened by the Massachusetts Medical Society and the *New England Journal of Medicine* in May 2008 to address physician dissatisfaction with primary care. The experts noted that the current reimbursement system rewards physicians and institutions for sophisticated technological procedures rather than for cognitive work and time spent with patients. They discussed the rewards that other countries have realized from investments in electronic systems and other health-related information technology. The panel underscored the need for the academic health community to focus on addressing the complex economic research and policy questions concerning improved access and quality of health care (72,73). At this writing, it is unclear whether public demand for postelection health care reform will succeed in countering entrenched industry interests.

## Professional Responsibilities

### Professional Duties

Professionals who act as "gatekeepers" to managed-care services are torn between containing medical costs and advocating for

resources likely to benefit individual patients. Seventy-five percent of physicians surveyed were concerned about the ethics of financial incentives intended to restrain testing, treatment, and medical referrals. Most of those surveyed—87%—believed that physicians should be empowered to discuss limitations of treatment coverage with patients (74).

Physicians worry that balancing the care of individual patients with stewardship of collective health care resources impairs their duty of loyalty to their patients. Many feel that their patients have lost trust in them over time (74). Caplan agrees that gatekeeping at the bedside undermines patient ability to trust caregivers. He advocates instituting public policies to assure ethical solutions to limitations on resources for patient care (75). Standardized treatment guidelines should be coupled with provisions that enable patients who find their treatment alternatives unreasonably limited to appeal those decisions (76).

Severely disabled patients may be particularly vulnerable to the constraints of managed-care systems. Patients with multisystem deficits who lack information about the potential benefits of rehabilitation care may be unable to overcome a bias to limit their treatment (76). Restricted access to care may fail to remedy characteristics of disease and disability that lead to social disadvantage. In a society that fosters individualism above mutual obligations to others, persons may be at particular risk if they are deemed incapable of contributing fully to society. A just health care system would not compromise quality and length of treatment for those who have chronic impairment (77).

Rehabilitation professionals have a duty to maintain personal and professional standards of competence in their field. Appropriate behaviors for professionals in many clinical fields are defined by discipline-specific codes of ethics. The commercial interests of health care providers who have complex business relationships with pharmaceutical, assistive device, and medical equipment companies invite increasing concern. Weber et al. describe the risks posed by pharmaceutical and biomedical businesses that provide gifts, free samples, equipment, medical devices, educational and informational programs, dinners, and retreats for medical professionals (78). Research shows that such relationships impact physicians' prescribing behavior (79). Commercial sponsorship of research, equity ownership in biomedical companies, and paid consulting relationships can create a culture of entitlement among providers. Restrictions on industry relationships and requirements for disclosure are becoming common in medical schools and teaching hospitals (80). Professional codes of ethics and business conduct must be enforced to protect the interests of patients and the integrity of professionals in a landscape of commercial interests (81,82).

Reports indicate that treatment provided in certain "joint ventures" is more costly than that delivered at similar facilities not owned by doctors. A study of doctor-owned physical therapy facilities in Florida noted a lower quality of care, fewer licensed therapists, and shorter patient treatment sessions than occurred in nonphysician-owned facilities (83).

Other professional interfaces may raise concerns (17). Dynamics within the treatment team can hamper the effectiveness of practitioners. Appropriate safeguards enable providers to question the recommendations or conduct of their co-workers or that of colleagues in other institutions. Individual team members may need support in disputing team norms or expectations. Practitioners should be permitted to decline roles with which they are personally uncomfortable, whether for reasons of professional expertise or personal values. They also have a duty to inform patients of treatments that have been recommended for potential benefit without scientific affirmation of efficacy.

Rehabilitation institutions should strive to serve disabled patients within the broader community. Institutions should widen and deepen their community engagement to reinforce integration of disabled persons and society. A virtuous institution conveys morally sound values by its responsiveness to families and broader social networks at the same time that it assures skillful care of patients in a fiscally responsible environment (84).

### Prevention Efforts

At times, disability results from preventable accidents or unwise lifestyle choices. For example, alcohol use and excessive speed may precede traffic accidents, and road injuries are more serious when seat belts or car seats are not used. Absence of helmets worsens head injuries in motorcyclists and bicyclists. Firearms produce severely disabling injuries.

The knowledge that so many of their patients have sustained disability that was preventable should mobilize rehabilitation practitioners to advocate public policies to enhance injury prevention, including gun control, helmet laws, and severe penalties against drunk driving and excessive speed. Although balancing individual rights and responsibilities with needs of the larger society is always challenging, it would seem that practitioners have an obligation to advance public policies that prevent needless disability. Certainly, rehabilitation practitioners are able to vividly describe the devastating long-term ramifications of spinal cord injury and brain injury.

## PEDAGOGIC ISSUES

Medical institutions and professional societies now include ethics topics in their educational programs. If ethics education is to be considered as important for rehabilitation students, as it is for students of other disciplines, faculty members need resources and time to familiarize themselves with the study of ethics. Certain professions and specialties (such as nursing, family practice, and internal medicine) have introduced an ethics requirement into their certification requirements. Rehabilitation accrediting agencies could do likewise (17). As the number of knowledgeable and committed instructors increases, rehabilitation practitioners might add formal certification requirements in ethics for students in specialty training programs.

Continuing education in rehabilitation should emphasize the study of ethics. Some rehabilitation institutions have initiated ethics grand rounds, and others have developed ethics committees similar to those in acute care hospitals to explore issues and advance understanding through discussion and educational workshops. A Scholars Program at the Rehabilitation Institute of Chicago and University of Illinois trains selected clinicians over the course of a year on traditional medical ethics, disability studies, and practical clinical topics for a certificate in disability ethics. Monthly interdisciplinary disability ethics seminars, quarterly grand rounds, and in-house ethics newsletters are part of this work (32,85). Similar programs will increase the ethical literacy of professionals.

Journal editors can encourage examination of clinical case studies and scholarly writing about policy aspects of rehabilitation. Organizers of medical ethics conferences could sponsor symposia and panel discussions on intriguing rehabilitation topics. Rehabilitation professionals could collaborate with community organizations to enhance discussion about ethical care. Education about the ethical challenges that confront patients, families, and practitioners has been noted to be invaluable for advocacy groups, institutional trustees, staff, patients, and family members (17).

## CONCLUSION

Rehabilitation practitioners will continue to confront significant moral challenges in the coming years. They must strive to ensure excellence of patient care predicated on sound scientific research and must assure that patients are treated with compassion and respect in an era dominated by financial strain and rapid technological innovation. The extent to which providers accept differences among people and the manner in which they attend to and understand patients and families are critical in today's complex and intimidating health care environment. Providing reassurance and comfort in conjunction with competent care has never been more important.

Health care practitioners have a duty to recognize and address inequities of our current medical system. As rehabilitation practitioners examine the quality and availability of medical resources, they must respond to society's failure to provide millions of Americans with access to basic medical resources. Rehabilitation clinicians should identify conflicts of interest in their practices and set exacting standards for professional conduct in the face of business opportunities and other temptations. Practitioners have a responsibility to ponder the role of medical rehabilitation in an era of limited resources. Conscious of the fact that some medical needs will remain unmet in a society that has other important needs, they must recognize and limit care of marginal benefit or excessive cost. They must assist in the development of sound public policy as American society attempts to balance the needs of vulnerable individuals with those of the larger society.

# Interactions with the Medicolegal System

Most clinicians in physical medicine and rehabilitation (PM&R) will eventually interact with the legal system. Many medical professionals carry negative feelings about being forced to deal with any type of medicolegal proceeding. Some even avoid clinical work that will more likely lead to depositions. Others feel there is no such thing as a truly “impartial” or “independent” medical evaluation. Much of this emotion arises from unfamiliarity and misunderstanding of the process involved. Although few practitioners relish this aspect of clinical practice, it need not be terribly onerous. The experience should be no worse than neutral if one is fully versed in the details. An overarching goal of this chapter is to remove some negative feelings about this type of work, not by artificially casting it in a favorable light but by desensationalizing the process through familiarization and preparation.

The most common types of medicolegal interactions include independent medical evaluations (IME), depositions, expert witness reviews, malpractice complaints, and issues relating to the structure within which physiatrists conduct their practices (medical staffs, employment and partnership relationships, and managed care provider contracts).

Physiatrists often perform IMEs, and even though attorneys may or may not be involved with IME cases, being available to perform them often leads to subsequent deposition, during which attorneys will necessarily be involved. Giving a deposition is quite commonplace and is a medicolegal interaction most of us will encounter. Because this experience is far removed from anything taught (or usually even observed) during training years for most physicians, a detailed review of this process is presented. Expert witness reviews are less common, and a brief discussion will suffice. Optimistically, malpractice complaints will not be encountered often, if ever, and are addressed only generally in this chapter. Practice issues are numerous and complex, and are therefore outlined only briefly.

## STANDARDS OF CLINICAL PRACTICE FOR MEDICOLEGAL EVALUATIONS

Medicolegal issues should be considered during the development of sound standards of clinical practice, including principles of review of records, taking the history, performing the physical examination, and generation of the report. Adherence to some commonsense guidelines will prove infinitely valuable if

a chart is later retrieved for medicolegal reasons. These issues should not, however, become the driving force behind how a practice is arranged. That is, one should not prepare reports as if their primary purpose is an eventual deposition. Above all, your routine clinical decisions should never be shaped solely by legal considerations.

## Review of Outside Records

A few narrative reports can be read at the time of the examination, but a large file should be reviewed earlier and then quickly scanned just before the history and physical (H&P). Radiographs should be studied if available. It is only necessary to review documents that are pertinent to your examination. For example, although you may note underlying cardiovascular disease, there is no need to detail the corresponding laboratory results, diagnostic test results, and the like. Your opinions in unrelated areas will not be legally admissible anyway, other than how they might directly affect rehabilitation issues. Do not discard records sent to you, however, even if they are peripheral to your assessment. An attorney may want to review every note ever sent to you. If some files are missing, suspicions may be raised that they were discarded for some ignoble reason. The records sent to you for purposes of an IME, that is, not for a treatment patient, should be retained for a minimum of 2 years. There is no universally accepted guideline for the time frame of record retention beyond that, and this may vary by jurisdiction.

## Taking the History

As always, it is imperative to be thorough while not becoming immersed in superfluous detail. The proper degree of completeness allows for full reproduction of the history months or years later, when direct recall of the patient is impossible. A chronological sequencing of events will facilitate later review. The line of questioning should be orderly: onset of the problem, ongoing and current symptoms and how they are changing, diagnostic testing and the patient's understanding of test results, past and present treatment efforts, history of similar problems, and pertinent, unrelated medical history. Your report might be the only documentation of an occupational or functional history, including the relationship of symptoms or job status to intercurrent events. Separate the effects of work-related and non-work-related injuries as much as possible. Include details of the effect of the patient's problem as it relates to physical, psychological, social, and vocational issues, where applicable.

## The Physical Examination

Third-party payers, defense attorneys, case managers, and others often balk at a “diagnosis” based solely on subjective patient reports without objective abnormalities. Where possible, generate a set of observations that are as objective as possible to counter future attempts by an attorney to dismiss all subjective reporting as unreliable. A common example is the distribution of trigger or tender points in a patient with a myofascial condition. It is helpful, years later, to have supportive documentation that the tender spots were at characteristic, reproducible locations described in textbooks (e.g., upper trapezius, levator scapula insertion, lateral epicondyle). On the other hand, if the patient reports a nonphysiologic pattern (e.g., severe tenderness with minimal pressure over every area examined), your description should be clear on this point. This type of reporting justifiably lends an objective air to what is inherently a subjective topic, that is, the reporting of pain.

Similarly, it will be more helpful to document joint or spine ranges of motion in terms of percentage or degrees rather than with modifiers such as *mildly* or *moderately reduced*. However, do not think that endless goniometric joint motion or computerized strength measurements or other data will by themselves lend additional credence to your report. A medicolegal report is useful because of the clear observation and objective reasoning used in reaching conclusions, not because of an overabundance of data.

When a physical examination finding is described as positive, specify for what symptom or sign it is positive. To illustrate, a straight-leg-raise test might cause pain. Was the pain shooting from the low back to the posterior thigh and then to the ankle, at 45 degrees of leg elevation, with an electric quality, or present at 80 degrees for only a mild pulling sensation in the hamstring area? The same pertains to Spurling’s maneuver, Tinel’s sign, and many others.

## The Report

In writing the IME report, after the introduction add a passage such as, “Mr. Smith was told that no treatment would be provided, and that the report would be sent only to you. He understood these points and proceeded.” This affirms the inherently different nature of this visit, in that a doctor-patient relationship has *not* been established.

The next section should note the origin and content of outside records. The pertinent findings can be cataloged either by date or content (e.g., summarize all clinic notes in order, then scanning studies, then electrodiagnostic findings). It is unnecessary to routinely provide details about each note as to date, content, or conclusions. It is acceptable with acknowledgment to refer to an outside record as a summary of prior testing and/or treatment. For imaging studies, your report should mention whether you reviewed the films and the radiologist’s report, the films only, or the report only. Keep in mind that a cross-examining attorney will be quick to point out that you are not formally qualified to interpret such studies, that is, that you are not a board-certified radiologist. If the actual films were not available, though, the same attorney would certainly

attempt to have you admit that it is useful to see the films yourself, since radiologists are not clinicians. There is no need to vary your own standard of practice in such cases, although as a rule, it is preferable to have viewed the images yourself.

All initial and any supplemental reports must be executed with word processing. Handwritten notes are unacceptable other than for brief items such as telephone messages, and perhaps prescription renewals and the like. This allows for legibility after photocopying, faxing, and recopying, as often happens with these documents in the medicolegal realm. A sound practice pattern is to dictate any note regarding direct patient communication. You will often be asked at the time of deposition if your habit is to dictate clinic notes after each patient, at the end of the office day, on the drive home after hours, or even at a later date. It is of course preferable to allow dictation time as part of each office visit to ensure highest recall, possibly eliminating the need for handwritten notes taken during the history.

To the extent possible, the history, physical examination, and your conclusions should be summarized logically and in as objective a fashion as feasible. Avoid judgmental or pejorative terms, such as *exaggeration* of symptoms, or *embellishment* of pain reports. These are impossible to support legally, as is the claim that the patient does not appear *legitimate*. In cases where there are no objective abnormalities, it is preferable to provide a dispassionate discussion about the lack of correlation between the symptoms and disability. For example, “The only impairment on examination or testing is minimal tightness of the left trapezius muscle. This does not explain the symptoms of chronic neck and low back pain, bilateral arm numbness, or the 9 months off work.” Similarly, it is important to outline those impairments that do account for signs and symptoms, such as “C7 nerve root abnormality on the right is confirmed by the reduced triceps reflex and strength and by the positive Spurling’s maneuver. This corresponds to the MRI scan finding of a right, low cervical disc herniation and to the EMG abnormalities.” This type of thorough recording of the thought process will simplify the chart review and deposition at a later date.

## INDEPENDENT MEDICAL EVALUATION

### Definition

The usual IME is arranged when one party desires to obtain an expert medical opinion from a practitioner who has never previously examined the patient. Your opinion is then used to help resolve a conflict between the patient and a third party, often an employer or insurance company. The IME request may originate from a company physician or worker’s compensation representative, an insurance company providing worker’s compensation coverage, a case manager for an insurance company, or an attorney representing either side in this conflict.

Although your medical expertise is requested, there is no doctor-patient relationship established under traditional law. Because of that, the IME report cannot be introduced into the legal record unless a deposition occurs. This means that an IME will more likely lead to a deposition than will treatment

evaluations. Another consequence of the lack of a doctor-patient relationship is that the IME physician is effectively shielded from malpractice suits arising from this activity. However, there has been recent discussion to reverse that “immunity.” A recent ruling in Michigan allowed a professional liability case to proceed against a physician who had performed an IME and who allegedly caused harm during the physical examination. Several courts have begun to require physicians who conduct examinations related to employment to notify patients of life-threatening conditions even if they are unrelated to employment.

### Ethics of IME

The underlying conflict between two parties mentioned earlier is the genesis of much of the controversy surrounding the medical ethics of IMEs. Take the example of a case manager for an insurance company that provides worker’s compensation coverage for a large manufacturer. It could be inferred that the case manager will remain in good standing only if she attempts to reduce the monetary consequences of the claims she oversees. The logical next step might be that she develops a list of IME physicians on whose opinions she can rely (i.e., who routinely determine that there is no impairment present, or if there is, that it is less severe and of less importance than the patient’s own physician believes, and/or that it is unrelated to employment factors). The converse applies to plaintiff attorneys, who know which practitioners and IME doctors usually find severe and long-lasting disability, even in the absence of objective impairment. The “independent” or “impartial” in IME is thus potentially compromised.

Some physicians have built a particular reputation for favoring either the defense side (companies, company physicians, case managers, worker’s compensation insurance companies, defense attorneys) or the plaintiff side (usually plaintiff attorneys). You could be asked during deposition what proportion of your legal work arises from which side. A physician who performs IMEs exclusively for one side may appear less objective to outsiders. Having said that, practice realities mean that it is virtually impossible to see anything approaching 50% from each side. Your reputation will be most well served if it remains crystal clear to all concerned that no one can reliably count on your opinion in advance; your conclusions in a given case will depend only on the particulars of that case.

Perhaps it is now more apparent why some believe this medicolegal world of IMEs and depositions should be avoided. Fortunately, judges, administrative law clerks, and mediators increasingly recognize a “boilerplate” IME and its authors, and will discount or even ignore its conclusions. Even strong-willed participants from both sides eventually understand that such one-sided opinions will not survive scrutiny and may cost more in the long run, as challenges and appeals drag out.

The straightforward, underlying principle for an IME, as with all of medical practice, is to always keep in mind what is in the best interest of the person you are examining. This would seem to sway physicians toward the plaintiff side of matters, since after all we should be patient advocates. In reality, an ethical physician will not be labeled as residing in either the

plaintiff or defense camp, attesting to a high level of objectivity and impartiality. Some examples will illustrate this principle.

### Case I

A young adult sustains a C6 complete spinal cord injury with tetraplegia from a motor vehicle accident. Months later, the insurance company wishes to settle its financial responsibility with a lump-sum payment. The patient’s attorney does not feel the proposed amount is nearly adequate to cover predictable and potential expenses for a lifetime. As a specialist in spinal injury medicine, your IME input has little to do with the impairment, which is not in question. You agree that long-term expenses are more likely to be met by rejecting a lump sum in favor of ongoing responsibility on the part of the insurance company. This “covers” the patient for unforeseen expenses even decades later and is in his best interest.

### Case II

A middle-aged machine operator sustains a back injury at work. A physician recommended by a friend determines that the patient is totally disabled indefinitely, perhaps permanently. Treatment includes three-times-weekly hot packs and ultrasound in the physician’s office. Diagnostic testing is normal, and your IME finds abnormal back mechanics from asymmetric muscle tightness but no additional underlying impairment. It is clearly not in the best interest of this patient (or of his family, of society, etc.) to allow indefinite disability, when a return to full work status would be a simple matter to achieve. Your recommendation is for a directed course of physical therapy to include manual techniques, restricted return to work while therapy is under way, with anticipated unrestricted work duty thereafter.

Impartiality is not difficult to conceptualize or attain. Each case is judged on its merits, with emphasis on objectivity. Reliable information can include your physical examination findings, diagnostic test results, laboratory studies, or even a surveillance videotape. If you are successful in achieving impartiality in all cases, you will develop a reputation that you do not automatically favor one side or another. Some third parties might not refer IMEs to you because of that, but that is business you are wise to do without.

### IME Without Treatment

IME without treatment is the most common type of IME referral. You will see the patient one time only, leading to an expert opinion about one or several questions. The question may be as deceptively simple, such as, “Was there a mild closed head injury?” In the musculoskeletal arena, several questions are usually posed:

- What is the impairment (the physiologic abnormality)?
- If an impairment is present, was it caused by the accident/injury in question?
- Will the impairment be temporary? Permanent?
- What disability arises from the impairment? In other words, what is the clinical relevance of the impairment?

- Have the diagnostic tests so far performed been justified?
- Are any additional diagnostic studies required?
- Has treatment to date been effective and warranted?
- What additional treatment is needed, if any?
- Has the patient achieved maximal medical improvement (MMI)? That is, would any further, formal medical input improve the impairment or the functional deficit arising from the impairment?
- Is the patient able to return to work with or without restrictions? How long will restrictions last, and will they be affected by your recommended treatment?
- In some states, what is the permanent impairment rating?
- For some cases, for example, after auto accident, is assistance with household activities needed? Is attendant care needed, and for how long?

### IME with Option to Treat

This is a less common type of referral. The evaluating and treating physicians hold quite different roles in the medicolegal world. That aside, there are times when the referring source arranges an IME soon after an injury because of uncertainty about whether an impairment exists. If you then identify a treatable cause of the symptoms, you might be asked, and it might make sense, to accept the treatment role. This occurs mostly when there has been no treatment so far, or at least no beneficial treatment. IME with treatment option usually implies that a less than typical adversarial component is present. Problems arise when the patient does not respond to your treatment as expected; in that case, the referring source might need to arrange yet another IME.

### Serial IME

An initial IME does not typically allow the physician to oversee testing or treatment. It can be frustrating to witness inadequate or improper care without the opportunity to rectify the situation. Some third parties will ask for follow-up IME(s), an intermediate step between opinion only and treatment. For example, you might determine with the first examination that only restricted work is possible for 6 weeks while the treatment you outlined is undertaken. The company could then request reevaluation at 6 weeks so that you can decide if unrestricted return to work is now feasible. Some patients are returned for numerous IMEs, especially if the recommended treatment has not been provided. Remember that your recommendations are not binding on the examinee or the treating physician. If a pattern of ineffective treatment persists, it is then incumbent upon the third-party payer to deny funding for any further such interventions.

## DEPOSITION

### Definition

A deposition is the process of taking your testimony, under oath, as part of a formal legal proceeding. It is usually a substitute for your appearance in the courtroom, and as such could

be thought of as a favor to you to keep you from having to disrupt your clinic schedule for court testimony. However, providing deposition testimony does not preclude a later court appearance.

Whatever you say in a deposition carries the full weight and responsibility of being in the courtroom itself, and you should handle it with equal respect. Although your examination results appear in a dictated report, the deposition allows for expansion and clarification of the content of your reports. As a physician, you will usually offer deposition testimony as an expert witness. A critical point to remember is that a medical expert witness may offer opinions, whereas a lay witness (nonexpert) may only testify as to facts, without lending interpretation.

A deposition is “called” (i.e., arranged) when a case has progressed (or regressed) to the point of legal action. These are typically civil cases involving insurance benefits—worker’s compensation, disability, automobile—or other payback carrying a perceived value to both parties. The fact that a deposition has been requested means that the differences of opinion have not been rectified during initial attempts at negotiation, compromise, and/or mediation.

If your testimony is needed for the courts, you might wonder why you are not simply served with a subpoena to appear there, as would any other witness. The answer, based on years of tradition, is that the attorney who wants your opinion does not want to inconvenience you. A courtroom date is subject to repeated cancellations and delays, a pattern that does not mesh well with running a medical practice. A physician could even turn into a “hostile witness,” whose answers are a surprise to the attorney. Depositions are therefore typically scheduled in your office, at your convenience, although standard practices vary by state and region.

### Scheduling the Deposition

Physicians are generally permitted by court rules to be compensated for their time in preparing for and attending depositions. Once you have experience with depositions, you might realize that it is wise to outline specific scheduling criteria. In the author’s practice, over 50% of scheduled depositions never take place and are canceled without regard to the havoc wrought on your clinic schedule. They are often canceled because attorneys use an upcoming deposition to “encourage” the opposing party to settle the case out of court.

Take the time to draft a form letter that is sent to an attorney’s office whenever deposition time is requested. The letter should outline your office protocol, including at least

1. *The fee.* A 1-hour minimum fee is common, perhaps with 15-minute prorated charges thereafter. If your practice leads to many brief depositions, for example, to review an EMG study only, you could consider a minimum fee based on a shorter time. The time for which you bill will include record review, conferences with the attorney, and actual testimony.
2. *Prepayment.* If your practice experiences frequent nonpayment of deposition fees after the fact, consider the

following: your office will not schedule the deposition until prepayment of 1 hour's fee has been received and has cleared at the bank. This guideline may seem harsh and could be needed only temporarily with certain legal offices, if at all.

3. *Time allotment.* It is impossible to predict with any accuracy the duration of a given deposition. Perhaps the most reliable indicator is the personalities of the opposing attorneys, which of course you typically do not know in advance. Generally, 45 to 90 minutes suffices, and it makes sense to schedule for the end of the day. Make sure your office confirms the deposition that morning, just in case it has been canceled or postponed without you having been notified.
4. *Cancellation policy.* The rationale for a cancellation fee based on the amount of notice is the likelihood of filling that slot with patient appointments. If a deposition is canceled, the only effective consequence is financial. The fee should be larger when short notice is given. If five or more business days' notice is given, for example, there may be no fee.

You can easily defend your fee and cancellation policies. The large block of time set aside for a deposition displaces revenue-generating activity. Although it is possible for an attorney to become so upset with these guidelines that a subpoena is issued for your court appearance in person, this is highly unlikely.

## The Day of the Deposition

On the morning of the day of the deposition your office should verify that the deposition is still taking place, as noted earlier. Allow about 15 minutes to review a small file and to meet with the attorney who requested your testimony. If the file is large, set aside additional time for its review. You should be familiar in detail with the chart material you generated; any of it is subject to exhaustive questioning. Take the time to highlight, underline, or flag pertinent passages, and keep these reports immediately available during the deposition. It is unnecessary to review in tedious detail any chart content beyond what you are directly responsible for (office notes, electrodiagnostic testing, outside test results that you ordered, physical therapy progress notes). Attorneys will typically not question you about reports from other clinicians, which are legally hearsay to you.

Your meeting with the requesting attorney before the deposition is to review the process and the general tone of your responses to typical queries. It is not to plot strategy or to engender an "us versus them" mentality. You should be informed about test results or evaluations concluded after your interactions with the patient, in case these are raised during testimony.

A small number of depositions are canceled after this "preconference" if it is apparent that your responses will not support the requesting attorney's case. Assuming the deposition proceeds, the lawyer who was not at the preconference might ask you about details you discussed, or if you arranged what your answers would be. It is wise to understand that you should not reach that level of specificity in a deposition preconference.

The typical deposition involves four people: the clinician, two attorneys, and a court reporter either typing along or speaking into a soundproof device. There could be three or more attorneys, each representing a different interest. For example, a patient may claim two work injuries and the employer might have changed compensation insurance carriers between the events. The patient is rarely present.

Some depositions are video-recorded. You will sit across from the camera, which will focus only on you regardless of who is speaking. The video technician becomes an additional participant, although sometimes replacing the court reporter.

To begin the deposition, you will be sworn in by the court reporter. The attorney who scheduled your testimony will make introductions and then likely briefly review your curriculum vitae and training/certification to establish you as an expert. You might be asked to provide an overview of the field of PM&R—be brief and use lay terms. Learn to slow your rate of speech and enunciate.

The main point of the deposition follows. The requesting attorney will take you through the *direct examination*. You will probably be asked how you came to examine this person, where the examination occurred, and about the dictated reports you generated after each visit, which will then be entered as evidence. Finally, you will be questioned directly about specific points of history, physical examination, test results, and your conclusions. Do not hesitate to refer to the file; no one expects you to remember details of an old case. If you have prepared properly, your responses will be prompt and confident. Your testimony should elaborate on yet be consistent with your notes. Inconsistencies will be apparent and will not reflect well on you. If a topic falls out of your areas of expertise, simply say so.

A cardinal point during deposition is that the physician is not on anyone's "side." You are there to represent a professional opinion, not as an advocate for one attorney or the other, the employer, or an insurance company.

As mentioned earlier, all courtroom protocol holds here as well. After one attorney poses a question, the other might object and then give reasons for the objection. Once the objection has been noted, you will be asked to answer the question anyway. Whether the jury eventually hears the question and your response will depend on how the judge later rules on the contended points.

You might be asked to comment on a "hypothetical" situation, the details of which will closely resemble the case at hand. Objections are universally raised to hypotheticals, citing lack of foundation, and that the proposed scenario will not stand up at time of trial. As always, wait until you are instructed to answer, and then do so.

When the first attorney has finished, the opposing party starts *cross-examination*. Only points brought up during direct examination are meant to be open for cross-examination. This alternating direct, cross, redirect, recross questioning can theoretically continue indefinitely, although in reality there are rarely more than two or three such cycles, of decreasing length. A common tactic here is for the cross-examiner to ask you questions that are said to require only yes or no responses.

This is usually an attempt to keep particulars of the case that are not felt to be favorable off the record. As an expert, you are there to provide opinions, not simple yes or no answers. Feel free to respond as fully as you feel is needed, even if the questioning lawyer objects.

It is natural to feel defensive at times during a deposition, usually during cross-examination. You might be asked why certain aspects of physical examination or diagnostic testing were not performed. Keep a cool head during the entire episode. These are tried-and-true tactics to put you off guard and perhaps to lead you away from an opinion that one lawyer would rather not hear. You should make every attempt not to take the proceedings personally. The attorneys will sometimes attack each other like worst enemies and then, after the deposition, plan where to have lunch. Only occasionally is true animosity present. Your goal should be to accurately represent your opinions and leave legal maneuvers to the attorneys.

## EXPERT WITNESS REVIEWS

You might be asked to review a file to provide your expert opinion about a particular issue. These often relate to possible overuse of physical medicine services (e.g., a practitioner provides hot packs and ultrasound three times weekly for several months to a patient reportedly injured in a car accident). If you agree that passive modalities are not indicated, your report will be used to retrospectively deny payment for those services. Given that the service provider could learn your identity, you must have the confidence and fortitude to perform this type of review.

Another form of chart review occurs with malpractice cases, which arise when a physician has been said to have breached, or failed to fulfill, a duty to the patient, and harm to the patient is the proximate result of that breach. In these cases, expert witnesses provide testimony as to the duty to the patient and its breach—the essential question is whether the standard of care owed by a physician to a patient has been met. Here, it is imperative that the salient issues fall within your areas of expertise. Medical practitioners usually review files on the side of the defendant, with the goal of showing there was no malpractice committed. As with IMEs, though, some witnesses are well known for providing an opinion that always favors the plaintiff. An “expert” who reliably favors one side is more a mercenary than an expert.

There are several points to consider before accepting a high-stakes review (e.g., a malpractice case). The foremost is whether you truly want to involve yourself in this type of work. Also, do you have time to provide a thorough and helpful opinion? You will need to scour the record for scraps that have so far eluded others or that you might be able to cast in a different light. This process can take hours. Finally, you must be fully honest with the attorney, even if your opinion is damaging to the case. If the practitioner who is being sued truly did not meet standards of practice, say so. It is extremely harmful for the case to proceed to trial based on opinions that will not withstand vigorous cross-examination.

## REMUNERATION FOR MEDICOLEGAL WORK

Medicolegal work can be lucrative. Physicians typically charge several hundred dollars hourly for expert review or deposition time. Where the money goes depends on the practice setting, but in all cases should be clearly delineated prospectively.

For a physician in a solo private practice, there is no controversy where the medicolegal fees go. In a group practice, this should be spelled out. Two obvious alternatives exist: either the funds go to the individual or to the practice as a whole. This same decision must also be made in the academic realm. Typically, if medicolegal work arises within the usual course of seeing patients in a practice, these funds go to the practice as a whole. Expert reviews by nature originate outside usual practice boundaries, and these fees may go directly to the individual physician (assuming the work is done outside normal work hours). In academia, there is often a set amount of “consulting” time allowed monthly, and medicolegal work could fall into that category, usually with approval of the department chair.

## ADDITIONAL CONSIDERATIONS

### Malpractice and Related Complaints

Most physicians will be served with malpractice complaints during their careers. As noted earlier, these cases focus on whether the physicians have met the duty to their patients and whether any breach is the proximate cause of harm to the patient. Such complaints, even for cases that are quickly dismissed, make it sound as if your entire professional existence is an abomination and the facility where you work would be better off razed. It is never more important to remember not to take this personally. The attorney who authored the offensive passages is acting in the best interest of the plaintiff within the framework of our present system. Never respond to the complaint yourself; never contact the patient or attorney directly, even if you thought there was a terrific doctor-patient relationship before the day’s mail arrived. Apparently, the feeling was not mutual. You will be represented by a defense attorney arranged by your practice, your hospital, or your professional liability insurance company. It is important to contact your insurer and any risk manager responsible for your facility or practice as soon as you become aware of a potential malpractice claim, so that the defense, and possible settlement, can be handled.

It is critical to know ahead of time if your legal defense firm generally believes strongly in proceeding with litigation rather than agreeing to negotiated settlements. Plaintiff attorneys typically do not realize reimbursement unless there is a payoff; that is, their getting paid is *contingent* on the outcome of the case. The plaintiff attorney’s pocketbook is best rewarded by spending as little time as possible on a case with the largest payment possible. This often means avoiding a trial. Defense attorneys are paid hourly fees, regardless of outcome. It may also be tempting for the defense to settle a

case rather than to litigate it (for the insurance company they represent, some payout now vs. the chance of a much larger one later). It is important to understand, though, that all such settlements appear as negative outcomes for the defendant physician, even if facts point to no wrongdoing. Various federal and state laws and rules require public notification of settlements and adverse decisions when malpractice has been alleged (e.g., the National Practitioner Data Bank records adverse judgments and settlement amounts and is routinely reviewed when application for employment or privileges is made by physicians).

Physicians may also be held liable when they employ or supervise others, such as therapists and nurses. When a physician takes on duties to the patient that do not involve treatment, the other assumed duties may result in claims and liability. Often there will be allegations against several professionals and their facility, after which the defendants may attempt to shift responsibility from one to another.

In managed-care situations, where payers are involved in establishing treatment plans and allocating the “quantity of care,” the liability issues become more complicated, as the quantity of care may be directly related to the quality of care, or at least have an impact on it. These cases often involve jurisdictional and procedural issues, in addition to the substantive questions, and are complex and time-consuming to resolve.

To minimize claims of malpractice and related matters, it is critical for physicians to

- Understand the duties they undertake to patients (such as providing care, supervising others, hiring others who are qualified to provide care in their stead)
- Understand the constraints imposed on them by managed care and payers in general
- Document all health care decisions and actions in the appropriate location (patient chart, incident report, etc.)
- Limit liability by contract when possible (e.g., clarifying in a managed-care contract that the physician has no liability for administrative decisions relating to utilization)
- Insure against claims when possible, coordinating that insurance coverage with the insurance provided by an employer, a facility, or others
- Obtain protection from others, when possible (such as indemnification in a contract where other parties may be responsible for actions that result in claims against the physician)
- Obtain consents from patients when necessary or appropriate (such as informed consent when risky procedures are involved or more than one treatment may be available, and consents to disclose patient information as to health status or other matters)

### **Abandonment**

Abandonment is another potential claim against physicians, in cases where a physician-patient relationship has commenced and the physician terminates it without giving the

patient adequate opportunity to locate another provider of similar services. This is often a situation involving non-compliant patients, patients who are disruptive to others, or a patient for whom no source of payment for services is available.

Ascertaining problems before a physician-patient relationship begins is ideal but not always feasible. Establishing rules and an agreement with the patient at the outset of the relationship that allow for termination in certain events may be helpful. In all events, it is essential to consult regulations of the appropriate Board of Medical Examiners and rules of any facility or practice in which a physician sees the particular patient, before acting to terminate the physician-patient relationship. You may be required to make yourself available for a time, perhaps 1 month, after notifying the patient of your intent to end the treatment relationship, in order to handle urgent or emergent matters.

## **PRACTICE STRUCTURE ISSUES**

Health care is a heavily regulated industry—various federal and state laws and regulations pertain to all facilities, personnel, and payment and insurance programs. The legal issues affecting psychiatrists and others vary with the relevant practice structure. The following discussion provides a brief overview of certain issues commonly encountered.

### **Medical Staff/Hospital Privileges**

When applying to join a medical staff, a physician should review the medical staff bylaws to become aware of how privileges are granted and how they may be revoked, suspended, or denied. The hospitals and other entities that grant and deal with privileges have the responsibility for ensuring that quality patient care is delivered through the medical staff and that responsibility gives the granting bodies great latitude in dealing with members of the medical staff on issues from quality of practice to behavioral issues (including impairment and substance abuse).

If economic issues are a component of obtaining or maintaining privileges, which may be the case when the medical staff privileges are an element of an employment relationship with a facility or hospital-based practice group, ascertain this at the outset of the relationship to determine whether you are willing and able to meet the economic aspects of the credentialing. If you do not believe that quality care can be delivered when you are required to see a high number of patients each day, for example, it is helpful to have that discussion with a prospective employer or facility administrator early on in the relationship, rather than after several unsatisfactory performance evaluations.

### **Group Practices and Employment**

When physicians join a partnership or group, they often become employees of that practice. Issues that should be evaluated, negotiated, and documented in a written agreement

include the following: duties, compensation, the term of employment, how the employment relationship may be modified or terminated, insurance coverage and responsibility for defending the physician if malpractice complaints are made, ability to provide services outside the practice (e.g., medical services, teaching, research), compensation for those services, any restrictions on competitive activity during or after the employment relationship, and whether medical staff privileges terminate if the employment relationship ends.

In addition, many employed physicians seek assurances that they will be permitted to acquire an ownership interest in the practice, or at least a share of the practice's profits, at some later time. The details of the negotiations vary greatly, depending on the particular practice group. For example, a small partnership taking on a new physiatrist early in her career may be unwilling to guarantee that she will become a partner, at least until the relationship has a chance to develop. On the other hand, a large and well-established practice group may have a well-structured approach for all new employed physicians, which establishes an equity (ownership) interest over time and which clearly delineates a schedule for how that interest is forfeited if employment ends. While employment agreements and practice documentation may look similar to many physicians who receive the offer to join a group, the rights of the parties as set forth in the final negotiated paperwork vary greatly, depending on many factors.

### Payment and Compensation Issues

Although legal issues relating to physician compensation are complex and cannot be adequately covered in this chapter, some key concepts should be kept in mind:

1. *Referrals and compensation.* Compensation for referrals is prohibited under several federal laws, including the Medicare statute and regulations. For physiatrists and their facilities and practice groups, entities that receive patient referrals as a matter of course, this means that relationships with referral sources must be carefully analyzed to ensure that a legitimate basis exists for any benefits (not just monetary compensation) that flow to the referral source. Similarly, as physiatrists make referrals to therapists and others, the restrictions prohibiting compensation for the referrals apply to these situations. In cases where a legitimate basis for payments cannot be established, regulators may attempt to challenge the payments as impermissible compensation related to referrals.
2. *Billing issues.* Although it may be intuitive to say that bills should only be generated by physiatrists for services actually rendered, the complexity of medical billing (exacerbated in situations where more than one payer is involved) presents a constant challenge for clinicians. As payers seek to reduce expenditures for medical services and to eliminate fraud from the system, audits and challenges to payment increase in frequency. Physiatrists and those who prepare

their billing must be knowledgeable as to what services may be billed, what restrictions are imposed by payers (such as prior authorizations and recertifications for prolonged courses of treatment), the processes for appealing when payment is denied, and the ability to recover from the patient, an employer, or others, if payment from one source is not forthcoming. In these situations, a clear understanding of the clinician's right to payment is essential, not only for the clinician, but also for the patient or the employer seeking the medical services, who may be an effective advocate for payment.

### Payer Contracts

Physicians often must be recognized by payers as "participating providers" before payment is made for clinical services. As payers seek to reduce expenditures for clinical activity, they have sought to keep the panel of participating providers small (making it easier to negotiate lower payment rates, justified by large volumes of patients seen by fewer clinicians). As health care costs continue to rise, there will be more pressure to reduce costs from payers, employers, patients, and others. Provider fees may decrease, capitated arrangements and other risk-shifting methods may change the types and quantities of services that are covered by health plans, and it is likely that receiving payment will become more difficult for physicians.

Physiatrists will need to

- Secure their participation in health plan provider panels
- Understand health plan limitations on coverage and payment
- Communicate those limitations to patients
- Limit their liability for claims related to administrative (nonclinical) decisions by health plan personnel
- Endure the administrative burden of dealing with payers, appealing payment denials, and so on
- Evaluate whether participation in various plans is economically justified

### Compliance

It is now customary in the health care industry for providers to adopt compliance plans to ensure that their operations comply with legal and ethical requirements. Physiatrists should thoroughly understand their obligations under compliance plans that relate to their activities. For example, if a physiatrist suspects that improper payments are being made to a referral source, that physiatrist must understand whether he or she is obligated to report that suspicion, and how that report will be handled. Education efforts are generally in place in large health care facilities to inform employees, medical staff members, and others of their compliance obligations.

### Antitrust

Although the topic of antitrust is beyond the scope of this chapter, medical professionals should have some awareness of its key concepts and prohibitions, especially as the health care

market is changing, aligning, and consolidating parties in ways that may violate antitrust laws.

Antitrust laws are intended to promote fair competition because consumers benefit from it. Antitrust laws prohibit monopolies, unfair competition, and unreasonable restraints of trade. In the current health care industry, practice and facility mergers that may adversely affect access to health care or the cost or price of health care are being challenged by antitrust regulators. When actual or potential competitors (such as two rehabilitation practice groups in a small geographic area) discuss fees charged for services, they may be open to allegations that they have “fixed” prices (tried to establish a floor price, which neither will undercut). This type of activity may result in severe consequences under the antitrust laws.

The changing nature of the health care industry does not lend itself to neat compliance with the antitrust laws. Although regulators are issuing current guidance to the industry, all providers of health care goods and services should exercise caution and obtain advice before engaging in discussions or transactions that may expose them to claims of antitrust violations.

# International Aspects of the Practice of Rehabilitation Medicine\*

*Not chaos-like, together crushed and bruised, But, as the world harmoniously confused:*

*Where order in variety we see, And where, though all things differ, all agree.*

Alexander Pope (1688–1744), Windsor Forest, 13

Rehabilitation Medicine (RM) in its more modern modalities is nearly a century old. (Older modalities such as spa treatments have been practiced for at least 300 years in Europe and even longer by the Aztecs in Mexico.) The field deals with various pathological disorders that may result in debilitating chronic conditions in patients of both sexes throughout their life span. It utilizes different treatment modalities, classical and innovative, of both low and high technological content. It entails interacting not only with the patient but also with the patient's family, work environment, and social milieu. As a result, rehabilitation professionals find themselves dealing with insurers as well as with legislative and political entities. RM is practiced in different parts of the world in different ways, depending upon the way both the individual practitioner and the entire rehabilitation system work.

In his talk at the first world congress of the society in 1952 in London (UK), Frank Krusen, the first president of the International Federation of Physical Medicine Society, cited a consensus of the participants by saying, “rehabilitation has become established as a new medical discipline which aims at restoration of the physically handicapped person... to normal life; that physicians should avoid an attitude of hopelessness or passive acceptance in the face of chronic illness or disability; that a dynamic approach to chronic illness frequently results in restoration of the chronically ill patient to a fair measure of self-sufficiency, self-respect and happiness; that physicians should be interested not only in adding years to life but also in adding life to years;...the physician should always consider the psychological as well physical problems (1).”

This chapter describes the practice of RM, as well as its related programs and activities in different geographical regions in the world, with the aim of explaining how the profession is perceived and put into practice. It also discusses the attempt to bring globalization and standardization of the profession through coordinated efforts (2).

## NORTH AMERICA: UNITED STATES AND CANADA

Globally, the field of physical medicine and rehabilitation (PMR) is committed to providing quality, compassionate, holistic, and team-oriented care to people with disabilities. Rehabilitation practitioners worldwide work to improve quality of life and enhance functional status through a combination of team work, dedication, and focused assessment of a patient's functional strengths and deficits within a medical and psychosocial context (3). American physiatrists have a long history of involvement in international PMR activity (4). The process of rehabilitation has been compared to “performing surgery from the skin out” (5) in that significant realignment, readjustment, and modification of a patient's environment and circumstances must be performed in order to compensate for impairments and functional deficits.

Within the context of international aspects of RM, this section focuses exclusively on the North American experience. It provides a concise overview of salient topics including a brief history of PMR focused on the development and evolution of the specialty in the United States, an analysis of the major practice areas and specializations among US physiatrists, demographics, consideration of cooperative and harmonizing projects, review of US residency training and educational matters, discussion of problems and recent challenges, elaboration on international outreach efforts such as exchange programming, discussion of the Canadian system of rehabilitation, and a forecast for the future of rehabilitation in North America.

Due to the preeminent role that the United States and Canada have played as a beacon of education and enlightenment for international medical education, this chapter would not be complete without a description of the importance of international educational exchange programs in PMR. Under the auspices of the International Society of Physical Medicine

\*The medical specialty of Physical Medicine and Rehabilitation (PMR) is referred to as such in the USA and Canada. Frequently, “PMR” and PMR are used interchangeably. In other parts of the world however (ie. Europe, Asia and many other international locations), the field is frequently referred to as Physical and Rehabilitation Medicine (PRM). For the purpose of uniformity and convention throughout this chapter, the specialty will be listed as PMR for when referring to the USA and Canada and PRM in other locations.

and Rehabilitation (ISPRM), the Faculty-Student Exchange Committee ([www.isprm-edu.org](http://www.isprm-edu.org)) is composed of international members. It is presently directed by a United States–based elected physiatric leadership and has been responsible for the building of global educational and humanitarian bridges in physiatry. This topic is elaborated upon later in this chapter (page 542).

The field of PMR in North America traces its origins to the mid 20th century when a seismic shift in thinking among health care providers occurred. Due to the burgeoning numbers of wounded and injured soldiers emanating from the war, a new emphasis was placed on the value of comprehensive, team-oriented care for people with disabilities of all types. The critical importance of ministering to and caring for people with disabilities all across America soon came to be recognized as an essential societal and ethical obligation.

During the early days of PMR, the specialization was actually divided into two separate and distinct areas: physical medicine *and* rehabilitation (6). Frank Krusen (1898–1973), the author of the first rehabilitation textbook and the founder of the first residency training program in physical medicine (Mayo Clinic), is largely credited for his pioneering role in physical medicine which focused on the use of electricity, heat, light, mechanotherapy, exercise, and other modalities in the alleviation of disease and disability. To differentiate physical medicine physicians from physical therapists, Krusen originated the name “physiatrist”—an appellation that has stuck to this day.

Almost simultaneously, the legendary Dr. Howard Rusk (1901–1989), responding to the need for help with the medical and functional restoration of wounded, disabled soldiers returning from active duty, started the field of rehabilitation within the United States. Rusk’s early pioneering efforts resulted in the establishment of one of the first comprehensive inpatient rehabilitation hospitals—the Rusk Institute of Rehabilitation Medicine at New York University.

Within the United States, physical medicine was first (primordially) recognized as a medical specialty in 1947, with the establishment of the American Board of Physical Medicine. In 1949, the word “rehabilitation” was added to the name. Over the years, PMR as practiced in the United States has evolved steadily. During the 1980s and 1990s, inpatient rehabilitation remained the mainstay of physiatric practice. More recently, there has been an increased shift in emphasis toward outpatient services.

PMR has prospered as a medical specialization, not only in mainland United States, but also in its territories. In Puerto Rico, for example, physiatry has grown by leaps and bounds. Dr. Herman Flax, one of the early pioneers of PMR in Puerto Rico, chronicled the history and development of the field over a 25-year period (7).

Within the United States and Canada, PMR is a medical specialty approved by the Accreditation Council for Graduate Medical Education that emphasizes prevention, diagnosis, and treatment of persons with disabilities who experience restrictions in function resulting from disease, injury, or symptom exacerbation. Practitioners of PMR are known as “physiatrists” and utilize a holistic and team-oriented treatment approach

which often combines medication, injections, exercise, physical modalities, and education customized to the patient’s unique requirements (6). PMR specialists offer care for persons with neuromuscular disorders who have acute and chronic disabilities. The overriding goal of PMR is to optimize patient function in all domains of life, including the medical, emotional, social, and vocational spheres.

With the “graying” and aging of the North American population, physiatry has grown significantly in its stature as a medical specialization and has been considered the “quality of life” medical specialization because of its unique focus on functional restoration and contribution to the conservative nonsurgical management of an aging population.

According to US Census 1990–2000 data, approximately 49 million noninstitutionalized Americans have a disability (one in five Americans). While there are many causes of disabilities, the most salient ones are those resulting in deficits of activities of daily living. Figure 22-1 below describes the most common conditions known to cause disabilities along with their respective prevalence.

Physiatrists in the United States practice within diverse and varied work settings. Although their work activities and specializations vary widely, there is still much consistency in work distribution. According to a 2005 study commissioned by the American Academy of Physical medicine and Rehabilitation

**FIGURE 22-1.** Physical conditions that cause disabilities. (From US Department of Census Statistical Brief. January, 1994. US Department of Commerce Economics and Statistics Administration.)

(AAPM&R), a majority of American physiatrists (according to time allocation) are involved in the general practice of PMR in the outpatient setting (50.1%), inpatient venue (23.1%), administration (9.8%), academic activities (4.4%), and research (2.8%). An AAPM&R comprehensive membership survey study conducted in 2002 revealed that for all respondents: 56.6% described themselves as “private practitioners” and 44.2% as “employed.” Approximately 0.8% of the above were both in private practice and employed.

Regarding physiatry employment settings for “employed physiatrists,” 47.2% worked in a hospital or rehabilitation institution, 41.8% in an academic setting, 9.4% as VA employees, and 6.1% as HMO employees. Many of the “employed physiatrists” worked in multiple areas. Regarding private practice physiatrists, 44.3% were in solo practice, 29.9% were in multiple specialty, 29.7% in single specialty, and 2.9% in other practice settings.

The pathway to becoming a board certified physiatrist in the United States begins in medical school. After completing 4 years of medical school, the medical school graduate enters an internship which is a 1-year sequence of coordinated rotations emphasizing basic medical skills within a transitional environment or an accredited training program in internal medicine, surgery, pediatrics, family medicine, obstetrics and gynecology, or some combination thereof. The 1-year internship period is followed by a 3-year residency training program in PMR.

At the conclusion of the 3-year residency, the qualifying graduate takes a board exam administered by the American Board of Physical Medicine and Rehabilitation (ABPM&R). Once this exam is successfully completed, the graduate takes another exam, the oral board, at the conclusion of the first year of practice. Recertification is required of each graduate every 10 years.

An increasing number of PMR residency graduates are choosing to pursue accredited fellowship training in PMR subspecializations by the ABPM&R including Spinal Cord Injury (SCI) (2002), Pediatrics (2002), Pain Medicine (2002), Neuromuscular Medicine (2006), Hospice and Palliative Care (2006), and Sports Medicine (2006). Other nonaccredited fellowships exist in many areas. The typical duration of these fellowships is between 1 and 3 years.

The ABPM&R has published residency training statistics that focuses on demographics, program size, and composition, as outlined in Table 22-1 (8).

Two key textbooks frequently utilized by physiatrists throughout North America (and the world, for that matter) are *Physical Medicine and Rehabilitation: Principles and Practice* by Joel DeLisa (9) and *Physical Medicine and Rehabilitation Medicine* by Randall Braddom (10). Other useful books include *Essentials of Physical Medicine and Rehabilitation* by Walter Frontera et al. (11). Useful handbooks for medical students and residents include *PMR Secrets* by Bryan O’Young et al. (12) and *PMR Pocketpedia* by Howard Choi et al. (13).

The two main American journals of the PMR field are *Archives of Physical Medicine and Rehabilitation* and *American Journal of Physical Medicine and Rehabilitation*. Starting January 2009, the American Academy of Physical Medicine

and Rehabilitation started publishing a journal entitled: *PMR, The Journal of Injury, Function and Rehabilitation*.

While the field as a whole continues to carry on its noble mission of providing quality, compassionate care for people with disabilities of all types, the specialization faces a major challenge from some insurers and third-party payers who have steadily decreased reimbursement. In addition, shrinkage of the allotted lengths of stay for a growing number of diagnostic categories has taken place. An illustrative example of this is that of an acute stroke patient who is allotted on average approximately 14 to 21 days of acute hospital rehabilitation prior to community discharge. Unlike many parts of the world, where such patients would be treated for 2 to 3 months, the US system of care offers much shorter lengths of stay.

Another major change and challenge has been the advent of prospective payment systems (14) for acute care hospitalization which has led to a shifting of patient care from the acute rehabilitation setting where rehabilitation is delivered in a focused concentrated fashion for approximately 3 hours a day to a subacute environment where the rehabilitation is less intense and often is of a “nursing home style” vintage. Throughout the United States, in order to promote vertical integration of health delivery systems, hospitals have transformed acute care beds into subacute care beds. In addition, many hospitals have purchased subacute care facilities including nursing homes and convalescence centers which serve a “surrogate rehabilitation” role.

Apart from the academic or hospital-based physiatric programs, an increasing number of private practice physiatrists (both solo practice and group practice) have now elected to focus a significant portion of their practice on pain management. This has occurred because of economic factors and arguably may pose a major threat to the roots and traditions of the field, since there may now be an evolving and diminishing number of available physiatrists to care for people with traditional disabilities such as stroke, SCI, and brain injury.

Within the educational and residency training realm, a growing and unprecedented number of graduating residents are pursuing fellowship training in PMR and a disproportionate number are choosing a pain management trajectory. Although some are restricting their practice to pain management, many still recognize the importance of remaining diversified and being prepared to care for persons with all types of disabilities. Since people with traditional disabilities (e.g., stroke, SCI, and Traumatic Brain Injury (TBI)) occupy an essential and ever growing portion of the health care bandwidth in the United States, rehabilitation “generalists” are very much in demand. A physiatrist’s higher calling of transcendent care and impassioned advocacy for persons with disabilities was recently noted in an issue of JAMA.

“As practitioners of the healing art, we are often swept away by the mundane minutiae of providing expert technical care to our patients. Often overlooked (however) is the human side of caring—that transcendent sense of seeing life through the eyes of our patients” (15).

The field of PMR continues to thrive and prosper within the United States because of the synergy that it has engendered

with other medical specialties and related rehabilitation disciplines. Since rehabilitation is recognized as a team effort, major bridges have been built with rehabilitation professionals across the spectrum including physical therapy, occupational therapy, speech and language pathology, recreational therapy, psychology, as well as rehabilitation nursing. More institutional and academic departments have integrated programs creating a fertile milieu for crossdisciplinary and transdisciplinary integration.

Above and beyond the clinical service delivery domain, physiatrists have teamed up with physical therapists, occupational therapists, speech-language pathologists, and other medical specializations including podiatry to carry out meaningful and impactful humanitarian objectives. A recent noted example of this is Operation Functional Recovery (OFR) which was an international project spearheaded by the ISPRM Exchange Committees ([www.isprm-edu.org](http://www.isprm-edu.org)) aimed at helping hurricane Katrina survivors. OFR also rendered assistance in other worldwide rehabilitation cataclysmic events including the tsunamis, earthquakes, and other natural catastrophes (<http://www.isprm-edu.org/human.html>). *Operation Functional Recovery: The Rehabilitation Community's Humanitarian Response to Hurricane* was in part the subject of a recent AAPM&R Focus Session (16).

On a worldwide front, the United States has taken the lead in organizing globalization initiatives in the domains of research, education, and humanitarian projects. Global initiatives in PMR present challenges for practitioners, yet offer many opportunities (17). A detailed discussion of international exchange activity in PMR appears in a later chapter in this text book.

Much like its Southern neighbor, Canada prides itself in providing quality, focused, functional-based care for citizens with disabilities. In Canada, after the completion of medical school (typically 4 years), physicians enter residency training through the Canadian Resident Matching Service. In 2008, there were 25 PMR positions available throughout the country, offered in 13 different institutions in the following provinces: Alberta, British Columbia, Manitoba, Nova Scotia, Ontario, Quebec, and Saskatchewan (18).

The Royal College of Physicians and Surgeons of Canada (RCPSC) accredits the postgraduate education programs for physiatrists. The program consists of 5 years of specialty education. During the first year, residents complete their basic clinical training. This consists of several off-service rotations, including internal medicine, surgery, as well as additional 1-month electives. This is then followed by 4 years of training in both psychiatry and additional rotations which are pertinent to psychiatry (neurology, orthopedics, rheumatology, etc.). During their final year, residents complete the Royal College certification examination. This consists of both a written component and an Objective Structured Clinical Examination (OSCE). In contrast to the United States, both components of the examination are completed in the residents' final year. Following successful completion of this examination, the physician is awarded the designation: Fellow of the Royal College of Physicians and Surgeons of Canada.

Most psychiatry residents also choose to complete 6 months of neuromuscular disease/electromyography training during their residency. This allows them to sit for the Canadian Society of Clinical Neurophysiologists electromyography examination which is administered to both psychiatry and neurology residents.

Canada, with a population of 33 million (19), currently has 373 physiatrists (20). As Royal College certified specialists, all physiatrists must participate in the RCPSC Maintenance of Certification program and must accumulate 400 hours of continuous medical education (CME) credits over a 5-year cycle.

The Canadian Association of Physical Medicine and Rehabilitation (CAPM&R, [capmr.medical.org](http://capmr.medical.org)) is the national organization for physiatrists in Canada. Its main goals are to promote education, scientific collaboration, and practice development among physiatrists. A 2006 survey by the CAPM&R indicated that 53% of physiatrists are in private practice. Of those, one third do not carry inpatients. Seventy-eight percent of physiatrists have clinical or academic university appointments. Similar to the United States, there has been a shift in the practice patterns of physiatrists to an outpatient focus. The inpatient system is moving toward a model where hospitalists/family physicians are the attending physicians of record, and physiatrists act as the consultant.

In contrast to the United States, where health care is more managed care driven, Canada has a universal health care system. In this model, every citizen has equal access to health care and is fully insured by the government for all medically necessary care. This has both advantages as well as drawbacks with respect to the inpatient system. It ensures that anyone who benefits from rehabilitation services will be given the opportunity to participate in a program. Another advantage is that inpatient length of stay varies depending on the needs of the patient, and this is decided by the physiatrist and the rehabilitation team. For example, in the stroke population, the average length of stay in Canada is longer (40 days) (21). By contrast, a drawback of Canada's social system is that wait times can be prolonged compared to the United States; the time from onset of stroke to inpatient rehabilitation admission is an average of 29 days (median: 15 days).

In conclusion, the North American contribution to international rehabilitation has been immense. As outlined earlier in this chapter, the humble origins of the field of PMR began in the United States with the work of dedicated pioneering physicians including Dr. Howard Rusk and Dr. Frank Krusen. Over time, the specialization has grown considerably.

## LATIN AMERICA

The origin of rehabilitation as a medical specialty in the developed countries and at the global level was linked to historical facts that promoted a great number of disabilities, such as the two World Wars in the first half of the last century. However, within Latin America the main impetus for the development of RM was the outburst of epidemics of transmissible illnesses

such as poliomyelitis, which is now eradicated in many of the region's countries. This brought about an improvement in sanitary conditions and a rapid development of rehabilitation as a medical specialty. These phenomena emerged simultaneously in many Latin American countries.

European countries such as England, France, and Germany, as well as the United States, served as models for many of the Latin American rehabilitation systems. Initially, the area of expertise was predominantly focused on aspects of Physical Medicine, and later on, RM started to develop as well. A continuous demand for the improvement in sanitary conditions and the possibilities for the development of the rehabilitation field at the national level hastened the development of these therapeutic modalities in this part of the world.

Scientific Societies of Physical Medicine and Rehabilitation were being established in the individual countries of Latin America and the Caribbean in the 40s and 50s, and consequently, the need of a Latin American Association that would bring these societies under one umbrella organization was recognized.

In 1961, during the first Mexican Congress of Rehabilitation, the distinguished Mexican Doctor, Alfonso Tohen Zamudio, brought together representatives from all Latin American countries. At that congress, they laid the basis of the Latin American Medical Association of Rehabilitation (AMLAR) and decided to hold the first AMLAR Congress in Mexico 2 years later in 1963, the second in 1967 in Peru, and the third in 1969 in Uruguay. Ever since that time, 23 congresses of the AMLAR took place. The AMLAR's presidency is in Uruguay, since the XXIII Congress, held in the city of Punta del Este (Uruguay), in October of 2008.

Rehabilitation in Uruguay has its origins in the 1940s. Prof. Alvaro Ferrari Forcade saw that there was a need for a functional measurement tool to assess the patient's status. He developed a scale that registers the patient's functional clinical state in three basic categories: somatic, psychological, and social. The scale assigns a score to each of the categories, in such a way that the results depict the patient's "profile of disability." Moreover, it allows for predicting the patient's functional outcomes (22,23).

In this way, the first functional measure of disability in Latin America was developed. Due to the fact that the implementation of this scale was done early in the development of RM in the region, its importance was not fully acknowledged at the time. This can explain the reason why this scale did not catch on while other such scales did, shortly afterward, in other parts of the world.

Latin America spans a large area with respect to political, geographic, demographic, and epidemiologic aspects. This is the reason for the varied degrees in the implementation of the RM and access to technology in the Latin American health systems. The demographic projections for Latin America and the Caribbean show that there will be progressive and dynamic changes during the course of next 40 years. These trends show a shift in the demographic profile, with significant aging of the population, due to a decrease in the birth rate and an increase in life expectancy for those over 60 years of age.

Even though in all the countries there is a marked increase in the population 60 years of age and above, the demographic change is not homogeneous and while some countries are still in an initial stage of increase, others are in a more advanced phase (24). Cuba in the Caribbean and the countries of the south cone (Argentina, Chile, and Uruguay) in Latin America, have a more aged population (Fig. 22-2), showing a more advanced transition.

This demographic change has a consequence from the epidemiological point of view. An increase in the elderly population will increase the prevalence of chronic nontransmissible illnesses related with the elderly. There is also an increase in the occurrence of nontransmissible illnesses linked to trauma and habits of life (accidents, social violence, accidents at work, and addiction) that coexist in the region with the transmissible illnesses. The increased number of high-risk newborns, along with malnutrition and the societal exclusion of indigenous ethnic groups (25), all contribute to the increase in the demand for qualified RM practitioners. The growing demand for rehabilitation professionals, and that these professionals be trained to the highest standards and continue their training after certification with a CME program, are the main focuses of the Scientific Societies of Rehabilitation and Physical Medicine of each country and AMLAR (26).

It is estimated that the population with disabilities in Latin America is close to 85 million people. Out of those, approximately 3 millions are in Central America (25). Although we know about the social and economic impact of disabilities in Latin America, it becomes more difficult to plan accurate strategies due to the lack of trustworthy epidemiological data. The reported data vary and it is not certain that they describe the true epidemiological situation in many of the countries, and neither are they statistically comparable. This is a consequence of using different disability concepts and different methodologies for gathering the information. Some countries have included questions regarding disability in the population censuses. Others have carried out specific surveys for disability considering the articles corresponding to the ICF (International Classification of Functioning, Disability, and Health). Generally speaking, the censuses have shown a lower prevalence of disabilities than the surveys. The discrepancy in the results is also due to what is considered a disability. Is disability based on the impairment a mainly medical concept? Or is it based on the functioning, integration, and the individual's participation with consideration to the patient's interaction with the environment? (This definition is based on the ICF paper "Measuring Disability Prevalence". Social Protection Discussion Paper. No. 0706. The World Bank. March 2007). This heterogeneity in concepts and methods makes the comparison of the results difficult when referring to the prevalence of disabilities in Latin America (Table 22-2).

RM has developed in Latin American countries but not uniformly. The availability of rehabilitation facilities is found in 78% of the countries. There is specific legislation regarding rehabilitative medicine in 62% of the countries and implementation of specific programs in 51% of the countries. The field

**FIGURE 22-2.** Percentage of the population of 60 years of age and more, in countries of Latin America and the Caribbean in the year 2000 and their projection to the years 2025 and 2050. (From *Demographic Bulletin*. United Nations Publications. 2003;XXXVI(72).).

is further hindered by very limited documentation of relevant data and limited research work. The practitioners are either specialists in rehabilitation or technicians consisting mainly of physical therapists, in addition to speech-pathologists,

psychologists, nurses, social workers, and occupational therapists. The medical schools and colleges offer little training and teaching in the field of rehabilitation. In addition to the factors mentioned above, there are additional roadblocks to

**TABLE 22.2** Prevalence of Disability in Countries of Latin America, According to Statistical Method and Disability Concept

Country	Method	Year	Disability Concept	Prevalence (%)

**TABLE 22.3** Rate of Physiatrists Per 100,000 Inhabitants in Several Countries of Latin America

Country	Physiatrists	Population	Rate
Argentina	240	3,260,130	0.6/100,000
Brazil	820	169,799,170	0.5/100,000
Chile	96	15,116,435	0.6/100,000
Colombia	200	42,888,592	0.5/100,000
Ecuador	120	18,755,650	0.6/100,000
Uruguay	68	3,314,466	2.0/100,000
Venezuela	400	27,483,200	1.5/100,000

the progress of RM in Latin America. Some of those problems are there are too few practitioners of RM in most countries; people with disabilities have a hard time integrating themselves into society; the private sector plays a preeminent role in the health care systems and is reluctant to pay for rehabilitative medicine (25); large sections of the population do not have accessibility to medical aid, let alone to rehabilitation facilities. There is a distinct association among disability, poverty, and social exclusion.

On the whole, the number of specialists in RM is in fact greater than the one registered by each national scientific society. Table 22-3 refers to the approximate numbers of physicians in some countries of the region, which have exceptionally low rates of specialists per inhabitants.

RM as a medical specialty was strengthened by unifying approaches to rehabilitative medicine which took place at the study group on The Training of Specialists, summoned by the PAHO/WHO in Santiago, Chile, in October 1969 (23).

There are three basic models of rehabilitative care in Latin America: (a) hospitals of acute care, (b) rehabilitation centers, or (c) community-based rehabilitation (CBR). Most countries have an emphasis on one of these models and subsequently affect the specialist's profile in each country. Uruguay is an example of a country that uses the rehabilitative model based on hospitals of acute care while promoting the interdisciplinary approach of the rehabilitation. They have recently started to work on rehabilitation centers related to pediatric care. Argentina and Chile have developed the models based on hospitals of acute care and rehabilitation centers. Nicaragua, El Salvador, Colombia, Argentina, and Guyana have developed the model based on CBR. Together with the help of non-governmental organizations, the respective governments are developing this model in Mexico, Ecuador, Peru, and Bolivia. Brazil is a remarkable example where all three models are used. The multidisciplinary diagnostic and therapeutic approach of disability treatment in Brazil has been an important factor in the development of rehabilitation in this country. The Rehabilitation Institute of the Hospital das Clinicas of Sao Paulo, the ABBR in Rio de Janeiro, and the Rehabilitation Institute of San Salvador were pivotal academic training sites in the specialty of rehabilitative medicine for Brazil and also for

the region. In the early 70s, Brazil was one of the first countries that developed a residency program in rehabilitation training (27). This residency program was used as a model for other such programs in others countries of the region.

The technology used in rehabilitation has improved from the 90s in several countries such as Argentina, Chile, Brazil, Colombia, and Mexico, especially in the field of orthopedic and neurological rehabilitation. Improvements in these countries had a positive effect throughout the region, in the practice of the specialty, in the academic training programs, and in the makeup of the specialist's profile.

Recently, AMLAR has begun to work toward unifying the specialist doctor's profile in the different countries of Latin America. They are trying to achieve this through the Societies of Rehabilitation and Physical Medicine of the individual countries, as well as in the specialist doctor's CME, the professional certification, and certificate reexamination. In the XXI Congress of the AMLAR (Venezuela, 2004), it was agreed that specialists in rehabilitation should be qualified to perform the following:

1. To identify and evaluate, in an integrative way, disabling conditions and processes
2. To devise a therapeutic program with the goals of preventing the subsequent deterioration in the somatic, psychic, and social realms of the patient
3. To implement and coordinate actions that will compensate for lost function by means of reeducation or compensation by functions that the patient still has, having as an objective to return the individual to the environment, with the highest possible level of independence
4. To acquire the skill and ability of prescribing, managing, and supervising the different procedures of the physical medicine and the therapeutic reeducation, making use of medical resources, technicians, family, and community
5. To work with an interdisciplinary team of experts in many diverse fields: nursing, physical therapy, occupational therapy, speech-pathology, neuro and clinical psychology, social workers, and others
6. To undergo special training in the use of exercise and physical modalities, orthopedic prescription, orthosis and technical helps, in the appropriate use of technology in rehabilitation. Training will be given in the use and application of instruments of functional measure and quality of life. In addition, special training in electrodiagnosis will be given
7. To conduct research in the areas of basic science, outcome measures and applied technology
8. To correctly handle the basic concepts of management and administration of rehabilitation services in all the levels of practice
9. To develop CME programs and to make sure that the practitioners will successfully complete specialty recertification, according to national and international regulations and standards
10. To practice in an ethically appropriate manner

In conclusion, the absence of trustworthy epidemiological data related to disability prevalence has hindered the development of specific programs of rehabilitation in most Latin American countries and it has impeded the access to such services. RM has developed differently in the various Latin American countries in accordance with various policies, legislative aspects, and technological developments. In the last decade, Latin America has improved its epidemiological data acquisition to make sure that the data is both more detailed and more uniformed for comparison purposes. A better understanding of the concept of disability in all of its aspects starting from the problems in functioning, of integration and participation in society in general, and by using better epidemiological sources seems to be the way toward standardizing and harmonizing the approaches used. This in turn will hopefully lead to the development of better policies and programs of rehabilitation. This will, in turn, improve the integration of the medical rehabilitation specialty in each of the country's health care systems.

## EUROPE

The first significant event in RM that took place in Europe was the International Physiotherapy Conference in Rome that took place from 13th to 16th October, 1907. After the conference, several text books on Physical Therapy were published in Italy and many other countries between 1925 and 1935. The development of therapy with physical methods based on medical-scientific origin is the continuation to the previous history of hydrotherapy and thermal treatments. These former treatments had already developed into a very important sector oriented toward the use of movement as an element of health and cure. These treatments were used by the Romans all the way through the medical modalities of Napoleon's army and the Habsburg Empire. In 1931, in Italy and in German speaking countries, authorities were appointed to deal with insurance for accidents in the workplace. This led to the development of functional recuperation and prosthesis. The terms used were physiotherapy and later physical medicine. In the 1950s, the terms recovery and rehabilitation were also used. The areas of clinical application have since become more and more numerous, but in particular the activity is aimed at the rehabilitation of disabled children, rehabilitation following traumatic lesions and injuries, and rehabilitation following peripheral and central neurological traumas and degenerative diseases.

Schools were opened for doctors and other rehabilitation-related professionals such as massotherapists and physiotherapists. The 1st Conference of Physical Medicine was held in Marseille in 1957, then in Milan in 1958. In 1962, the European Union of Medical Specialists (UEMS) recognized physical medicine as an autonomous discipline under the name of physical and rehabilitation medicine or PRM. A characterizing element of that period, which was very rich in clinical experience and innovative intuition, was the development of many distinct methodologies such as Brunnstrom, Vojta, Bobath, Kabat, Salvini-Perfetti, Maigne, and others.

In these years, the first national societies of physical medicine in Italy, France, Portugal, Belgium, and Holland were formed. In addition, a European Academy was formed on the 25th April 1963 in Brussels, and with an officializing act by the Royal Belgian Bulletin, the European Federation of Physical Medicine and Rehabilitation was formed, which initially grouped together the nine national societies which were already present on the continent. Large areas of research developed. One of the first areas of interest involved the treatment of scoliosis, the care and treatment of subjects with war amputations and work injuries, and the thousands of cases of poliomyelitis that were prevalent in the 1950s.

After that, the field developed rapidly and spread over all of Western Europe. The development of rehabilitative medicine was helped by important governmental legislation as well as by the Council of Europe and then by the European Union (28). The European Federation, with the UEMS and the Academy, published the first White Book in 1989 (29). A new edition came out in 2006 (30,31).

Some of the reasons for the great strides in both the scientific and operational advances in RM have been

- The contribution and integration of “adjunct” health workers, in particular, nurses, orthopedic technicians, physiotherapists, speech therapists, and occupational therapists to RM.
- The thrust and richness of the commitment and the proposals by disabled persons associations and their families who have been able to transform pain, damage, and possible desperation into a clear request for services and treatment. Thus, requiring the national and European community to carry out their cultural as well as economic duties.
- The contribution of many institutes, religious and private foundations who have dedicated themselves to this sector, must not be forgotten.

On a global level, the WHO based in Geneva and other organizations are pushing to gain attention for the problems of people with disabilities and for the documentation of rehabilitation resources in countries world.

The European Parliament has taken a positive interest in policies that safeguard the rights of disabled people. The “Recommendation 1185 (1992)—Rehabilitation Policy for the Disabled” (28) was decisive. The European Union decided upon the value, content, and quality that must be guaranteed to all patients at each medical examination.

The European Definition of a Medical Act is “The medical act encompasses all the professional action, e.g., scientific teaching training and educational, clinical and medico-technical steps to promote health and functioning, prevent diseases, provide diagnostic, therapeutic and rehabilitative care to patients, individual groups or communities and is the responsibility of and must always be performed by a registered medical doctor/physician or under his or her direct supervision and/or prescription.” (3 November 2006—UEMS Meeting in Budapest).

There is wide consensus on the importance of rehabilitative medicine on the ethical, cultural, and political level on the continent. For this reason, there is a progressive improvement at the operational level in both research and treatment and services offered in the 27 countries of the European Community. There are, however, some differences between countries due in particular to different economical conditions. As a result, the PMR and all of its professionals have the responsibility to communicate and understand all pertinent aspects in the Community (32), in addition to their daily clinical tasks of assisting individuals and solving their problems.

In fact, all over Europe great changes have taken place in the perception of health. Disorders, symptoms, and phenomena that perhaps in the past were supported and considered inevitable are now no longer accepted and demands are rightly made for any treatment that can eliminate or alleviate such problems. RM is, more than any other medical specialty, in the center of this transformation. Scientific breakthroughs can potentially modify disabilities that previously were not successfully treated and that have spurred a growth in the demand for rehabilitative medicine services (33).

The rights of the individual to a treatment for any problem related to his or her overall biopsychosocial situation, limitation, or disability that alters even only transiently his or her autonomy, self-sufficiency, and self-determination is the starting point of all rehabilitation activities and associated professional and organizational responsibilities (34). Social Participation is a term that aptly represents the individual's fulfillment of these rights (35). The individual's rights are inextricably bound to the *duty of society* to guarantee every person all possible treatments for maintaining, for as long as possible and at the highest level possible, personal autonomy. It is also society's duty to optimize and at the same time verify the appropriate use of the many available rehabilitative instruments with respect to parameters of efficacy, efficiency, and sustainability.

Physiatry in Europe is not a very old discipline, and precisely for this reason, it has vigorous roots. Its taproot, which as always in medicine is part science, part research, experience in the field, and critical reflection, highlights the duality of the physical and the rehabilitative components of physiatry. The *physical* component deals with the whole physical environmental context which interacts positively or negatively with the person and his or her problems, while the *rehabilitative* component aims to restore balance to the physical components by means of intervention. These two components act synergistically with respect to research and in clinical practice. In the current transformation of health care demands, rehabilitative medicine is showing its maximum potential and enormous intrinsic value.

The traditional medical intervention approach focuses on a disease process. By contrast, physiatry in both practice and research never separates disease processes from the individual as a whole and his or her active and passive relations with his or her surrounding context. Indeed, the psychiatric approach

is constantly based on the awareness that the determining factor is precisely this *relation* and not the isolated biological conditions.

Diagnosis, evaluation, and prognosis in traditional medicine are based on analyzing separate symptoms and pathological factors and integrating them all into an overall picture. By contrast, a primarily rehabilitative view considers the *whole* person in all aspects, functional, emotional, motivational, and behavioral as the *primum movens* using these parameters for determining the modality, limits, and aims of the care of the patient. Since a patient's health status is the result of a large and complex number of different factors, the therapeutic pathway to reach the best possible level of recovery and maintenance must be equally complex, synergic, and multifactorial and that is the goal of RM.

Since the 1970s, several forces converged which have stimulated a renewed focus for the work of rehabilitation professionals. These include several European initiatives. Among them are (a) the disability classification systems of the WHO, including the International Classification of impairment, Disability and handicap and the ICF (36); (b) a recent international document on CBR and (c) the Council of Europe's Directives (37).

The ICF has formalized for all medical practitioners a language and a way of thinking that were always ours in rehabilitation. The research and the applications that are currently coming to fruition provide new elements for growth in all fields, as is happening with the Disability and Rehabilitation Action Plan WHO 2005/2010 "A world for all" (38). PRM claim to be qualified for the overall study of the function and health of a person (and of a community). They are also qualified to do research into those elements that characterize and modify the person and his or her relational context, and for managing the multidisciplinary and multiprofessional collaboration necessary both in order to carry out this research and for performing the therapeutic interventions (39).

The task of PRM is to help the functionality of a patient reach an optimal level, compatible with the potential and aspirations of the patient, using some specific therapeutic strategies:

- treating impaired body structures and functions,
- overcoming obstacles arising from changes in body functions, limitations of activities, or restriction to participation,
- preventing the onset of further disability and limitations in functioning.

The central point for PRM is the *Individual's Rehabilitation Plan* which collects and distills all the previously mentioned concepts and concretely expresses the true epicentric status that the individual must hold in all stages and in all interventions. The Individual's Rehabilitation Plan represents the possible pathway for reaching an optimal state of well-being, participation, and health. It combines the skills and duties of the various members of the *Team* (which is the indispensable unit for rehabilitation care) and the different treatment settings and structures for the different periods of this process.

The Individual Rehabilitation Plan defines, recapitulates, and verifies the entire content of this tangible pathway toward recovery of as much autonomy as possible; it must, above all, be experienced and agreed by the individual, but it must also be based on precise and validated scientific elements.

Rehabilitation, both on an individual and on a population level, must represent the meeting point between scientific evidence and epidemiological evidence. Using indicators of health in different countries (e.g., the European community as a whole), we can derive a plan that could list the priorities of possible interventions in relation to their efficacy. This is undoubtedly a fundamental aim for us all (40).

From the point of view of health care, there is a need for the diagnostic, prognostic, and therapeutic evaluation to have a unifying capacity, collecting together all the different elements in order to best understand the way in which the different pathologies, biological, psychic, emotional, relational, and affective problems, can interfere with the person's functions, potential, and desire to regain activity and health.

In brief, European Health System must move from emphasizing the epidemiology of the disease to stressing the epidemiology of limitations in participation, which is much more significant in terms of real impact.

The *WHO's ICF*, is nowadays the best instrument, on both the clinical and community levels, for integrating individual and population data. It offers a uniform methodology of interpretation and representation for all the determinants of the

health status of a person and of a population. The European Union provides the means for representing and collating all the data on the health of its member countries, in scientific, administrative, social policy, cultural, educational, and occupational terms (35).

### Education and Training

PRM is an independent medical specialty in all European countries, except Denmark and Malta, but its name and focus varies somewhat according to different national traditions and laws. Training usually lasts for between 4 and 6 years depending on the country (UEMS Charter on Training, EC Directive 93/16/EEC, 5 April 1993) (Table 22-4). The number of specialist per inhabitants is not uniform throughout Europe. The numbers range from a low of less than 0.5 per 100,000 inhabitants in the United Kingdom and Ireland to more than 4.5 per 100,000 inhabitants in Portugal and in the Czech Republic (Table 22-5). Specialists in PRM have freedom of mobility across UEMS member states, but require certification from the national training authorities. Those with national certification are eligible to be certified by the European Board of PRM. The European Board of PRM has developed a comprehensive system of postgraduate education for PRM specialists that consists of

- A curriculum for postgraduate education containing basic knowledge and the application of PRM in specific health conditions

- A standardized training course of at least 4 years in a PRM department and detailed documentation in a uniform official logbook
- A single written annual examination throughout Europe
- A system of national managers for training and accreditation to foster good contacts with trainees in their country
- Standard rules for the accreditation of trainers and a standard process of certification
- Quality control of training sites performed by site visits of accredited specialists
- Continuing professional development (CPD) and continuing medical education (CME) within the UEMS. Recertification occurs every 10 years.
- Assessment and review of interventions
- Prognostication
- Physical treatments
  - Manual therapy techniques for reversible stiff joints and related soft tissue dysfunctions
  - Kinesiotherapy and exercise therapy
  - Electrotherapy
  - Other types of physical treatments including ultrasound, heat and cold applications, phototherapy (e.g., Laser therapy), hydrotherapy and balneotherapy, diathermy, massage therapy, and lymph therapy (manual lymphatic drainage)
- Occupational therapy to
  - analyze activities, such as those of daily living and occupation, support impaired body structures (e.g., splints)
  - teach the patient skills to overcome barriers to activity of daily living (e.g., adjusting the private facilities)
  - train in the presence of impaired function and cognition
  - enhance motivation
- Speech and language therapy within the framework of complex specialized rehabilitation programs
- Dysphagia management
- Neuropsychological interventions
- Psychological assessment and interventions, including counseling
- Nutritional therapy

### Interventions in PRM as mainly Accepted in European Countries

A PRM specialist can either perform or prescribe the given intervention. Interventions include

- Medical interventions
  - Medications aimed at restoring or improving body structures and/or function, for example, pain therapy, inflammation therapy, regulation of muscle tone, improvement of cognition, improvement of physical performance, or treatment of depression
  - Practical procedures—including injections and other techniques of drug administration

**TABLE 22.6** Activities of PRM Doctors in EUROPE 2005 ESPRM

United Kingdom		

- Disability equipment, assistive technology, prosthetics, orthotics, technical supports and aides
- Patient education
- Rehabilitation nursing

PRM specialists work in both public and private health services to varying degrees. This varies between different European countries (Table 22-6).

### The European Bodies in PRM

#### UEMS PRM Section

The purpose of the UEMS PRM section is to promote the specialty in a professional capacity and to harmonize the specialty at the European level through specialist training and continual professional development through revalidation. They work to develop clinical standards in practice and to help facilitate the required research to develop it further. They are accountable (as with other specialties) to the UEMS and have started to work closely with the European Commission and the Council of Europe. They have three main committees under an Executive Committee.

- Training and Education Committee (a statutory committee—the European Board of PRM)
- Clinical Affairs Committee
- Professional Practice Committee

#### The Académie Européenne de Médecine de Réadaptation—European Academy

This body of up to 50 senior doctors in the specialty across Europe was created in 1969. Academics are invited on the basis of their distinguished contribution to the specialty, particularly to its humanitarian aspects. The aim of the Académie is to improve all areas of rehabilitation for the benefit of those who need it.

#### The European Society of Physical and Rehabilitation Medicine

The European Society of Physical and Rehabilitation Medicine (ESPRM) was founded in 2003 and is concerned with research and teaching of PRM in Europe. It succeeded the European Federation of Physical Medicine and Rehabilitation (established

in 1963) and aims to coordinate European activities and be a vehicle for scientific exchange. The society offers individual membership to all eligible PRM specialists and federated membership of the national PRM societies in Europe. Individual membership is free of charge. The ESPRM is establishing an interactive electronic platform ([www.esprm.org](http://www.esprm.org)), where information can be found on research projects, grants, and funding. The Web site offers updated information about courses, congresses, exchange funding, etc.

The ESPRM organizes biennial scientific congresses. The main topics of the previous congresses were clinical standards, measurement of outcomes and effective interventions in neurological rehabilitation, musculoskeletal rehabilitation, and amputee rehabilitation, advances in PMR—traditional and modern concepts, evidence-based rehabilitation, PRM in lung transplant and in diabetes mellitus, and the scientific basis of PRM research.

### MEDITERRANEAN, MIDDLE EAST, AND AFRICA

*The creation of the “Mediterranean Forum of Physical and Rehabilitation Medicine” (MFPRM) and its role in the development of Rehabilitation Services in the Mediterranean Countries:* Over 20 years ago, Rehabilitation experts from around the Mediterranean Basin, expressed their wish to do something to promote PRM and rehabilitation services in the Mediterranean countries. They wanted something to unite them as a family, a mechanism for mutual help and for strengthening their relationships. The first step was taken in Israel when Prof. Haim Ring proposed to the Israeli Association of PRM to organize the first Mediterranean Congress in Herzliya, Israel. This First Mediterranean Congress of PRM took place in May 1996. The symbol chosen was a map of the Mediterranean Basin with a dove of peace flying above and the motto of “Rehabilitation without frontiers” underneath. About 500 people from 42 countries from all continents participated. The Mediterranean Basin was especially well represented with participants from 11 countries. During that congress, a special meeting took place under the title: “A Mediterranean PMR Society: Is it viable?” It was decided at that meeting to continue all agreed upon activities and to hold meetings every 2 years. Subsequent meetings were held in Valencia, Spain; Athens, Greece; Syracuse, Sicily; Antalya, Turkey; and Vilamoura, Portugal. The number of participants grew from one conference to another. More importantly the number of representative Mediterranean countries grew steadily. During the 3rd Mediterranean Congress of PRM, the MFPRM was created. At the 4th Mediterranean Congress, the MFPRM statute was accepted. It contained the following provisions:

#### A. Mission and Goals:

1. MFPRM will be the scientific Mediterranean body for physicians who work in the fields of PRM in the countries surrounding the Mediterranean Sea as well as adjacent countries.

2. MFPRM will facilitate exchange of information regarding different aspects of rehabilitation research, multicenter trials, national and regional projects, and meetings and congresses throughout the Mediterranean Basin.
3. MFPRM will organize a biennial Mediterranean Congress of PRM in one of the countries that has active members in the Forum.
4. On a national level, MFPRM, in close cooperation with the national society of PRM, will influence governments to support initiatives and collaborations in the field of teaching, development of services, and research in PRM. It will provide governments with information about the contents and evidence-based efficacy of PRM.

B. Membership in MFPRM:

MFPRM is open to all qualified physicians who specialize in PRM and work in one of the countries bordering the Mediterranean or in one of the adjacent countries. Membership is free to all.

- C. The society is conducted by a board and a general assembly is organized every 2 years during the Mediterranean Congress.

In November 2005, the *Euro-Mediterranean Rehabilitation PRM School* opened its gates, under the auspices and involvement of the MFPRM, and was successful in part due to the active and successful efforts of Franco Cirillo and Alessandro Giustini. The school is run by a consortium consisting of the Italian PRM Society “SIMFER” and the Sicilian regional group members of MFPRM. In addition, the school is supported by a number of Sicilian Universities and the Syracuse Regional province authorities. The Scientific Committee is made up of members from the Scientific Associations. The school is financially supported by the Syracuse Town Council, the regional province, and the Tourist Board of Syracuse. Thanks to these contributions, the students need only to pay their airfare. Tuition, food, and lodging are free. Every year, the curriculum focuses on a specific topic and is presented by specialists in that area. The courses are a week long and English is the official language of the courses. The first year’s sessions were on education and on research in rehabilitation. In November 2006, the second session took place. The main topic of the course was “Pain and Mobility.” Thirty-six young professionals, members of the Forum, from Italy, Greece, Egypt, Portugal, Serbia, Israel, Slovenia, Turkey, and Spain came and received both theoretical and practical training. The third session was held in November 2007 and hosted about 40 students. The topic was “Emergency Medicine & Rehabilitation.” At the 6th Mediterranean Congress of PRM which took place in Vilamoura, Portugal, in October 2006, all participants from developing countries were waived registration fees and participated for free. The 7th Mediterranean Congress of PRM was held in Portorose, Slovenia, in September 2008. The number of members of the MFPRM, under the presidency

**TABLE 22.7 PRM Manpower in Mediterranean Countries in 2006**

PRM in Mediterranean Countries—October 2006				
	In Training	In Practice	Per 100,000 in h	Inhabitants
Croatia	41	288	7.5	4,381,000
Greece	32	174	1.87	11,000,000
Spain	280	1,600	4.18	45,000,000
Italy	500	5,000	9.8	56,000,000
Slovenia	20	70	4.49	2,003,000
Portugal	48	489	5.18	10,356,000
France	120	1,816	3.23	60,000,000
Turkey	300	1,500	1.18	72,000,000
Cyprus		5+4	0.9	1,000,000

Servia	120	600	7.59	10,000,00
Israel	30	150	1.2	7,000,000
Egypt	50	600	2	75,000,000
Jordan	14	65	1.44	5,500,000
Romania	70	700	3.5	22,000,000
Algeria	90	285	1.14	32,790,000
Albania		20	0.65	3,100,000
Totals	1,739	13,412	3.54 mean	427,530,000

of Prof. Nicolas Christodoulou, residing president since 2002, has been continuously increasing. The members hail from the following countries: Portugal, Spain, France, Italy, Malta, Slovenia, Croatia, Serbia, Bosnia, Montenegro, Albania, Greece, Bulgaria, Romania, Moldova, Turkey, Cyprus, Syria, Lebanon, Israel, Jordan, Egypt, Tunisia, and Algeria. In the course of the six Mediterranean congresses it became possible through interactive sessions to collect information about the PRM manpower in the Mediterranean countries and to design the desired model of rehabilitation services that would be presented to the governments in the area. Table 22-7 illustrates the manpower situation in the Mediterranean countries which responded to the survey.

The median number of professionals in practice and in training in 2006 was 3.54 per 100,000 inhabitants, but the mean desired number according to the needs, as expressed by the participants in the survey, is 4.29 per 100,000 inhabitants. This means that in the Mediterranean Area at least 3,200 additional specialists in PRM are needed. The conclusions reached from the survey resulted in a recommendation for a minimal network of medical rehabilitation services to be developed in each Mediterranean country. The model of such a network is as follows:

1. *Phases of rehabilitation intervention:*
  - a. Intensive rehabilitation
  - b. Completion of the recovery process and of the rehabilitation project
  - c. Maintenance and prevention of further disability

2. *Organization levels of Rehabilitation Services in three phases:*
  - a. hospitalization
  - b. residential
  - c. outpatient
3. *Network of rehabilitative services delivered in*
  - a. Long-term hospital settings
  - b. Outpatient recovery and functional reeducation clinics and hospitals
  - c. Extra-hospital rehabilitation settings
  - d. Outpatient rehabilitation centers
4. *Intensive rehabilitation interventions delivery:*
  - a. Multiple specialty and/or single specialty hospital facilities
  - b. Extra-hospital rehabilitation settings
5. *Rehabilitation Centers focused on special PRM branches:*
  - a. Spinal cord injuries
  - b. Pediatrics
  - c. Neuropsychological problems
  - d. Traumatic brain injuries (including strokes)

It was mutually agreed by MFPRM members to try to implement this simple basic model of a rehabilitation services network in each country. It was also agreed upon to further the development of rehabilitation services, until each Mediterranean country implements comprehensive rehabilitation services. MFPRM has gained the support of world and international bodies. Since the first Mediterranean PRM Congress in Herzliya in 1996, all of the “in-between congresses meetings” of the International Rehabilitation Medicine Association (IRMA), the International Federation of Physical Medicine and Rehabilitation (IFPMR) and their merged body: International Society of Physical and Rehabilitation Medicine (ISPRM), as well as those of the European Federation of Research in Rehabilitation (EFRR), take place during the Mediterranean PRM Congresses (41–43).

### Middle East—Kuwait

There is a very active PMR Society which has organized several scientific events under the presidency of Dr. Abdulla Eyadeh. The main PRM premises are in the PMR Hospital in Kuwait, which is an 81-bed facility with Dr. Abdulla Eyadeh as the head of the institution. It caters to persons with various physical disabilities from Kuwait as well as from other Middle Eastern countries. It has several specialized services and is also a center for various academic activities. The PMR Hospital was granted accreditation in 2004 after having fulfilled the guidelines set by the Kuwaiti Ministry of Health. The First Conference of the PMR Society of Kuwait and the First Regional Meeting of ISPRM was conducted in April 2000. The PMR Hospital in Kuwait has, to date, organized eight workshops and conferences since 2001. There is an expansion of the diagnostic facilities in the hospital which already has a fully equipped EMG and Urodynamics clinic. A comprehensive cardiopulmonary rehabilitation program has been started at PMR Hospital in Kuwait as well. This program aims to improve the cardiac health in those with high risk factors and rehabilitates cardiac and pulmonary patients (44).

### Saudi Arabia

The existing rehabilitation services in the country organized the 4th National Rehabilitation Symposium and the Regional Meeting of the ISPRM at the Armed Forces Hospital in Riyadh, Saudi Arabia, in February 2001. There were 25 speakers from Saudi Arabia as well as lecturers from other Arab and non-Arab countries. Numerous relevant topics were presented reflecting the rehabilitation activities within the country. These included recent developments in stroke, traumatic brain injury, and SCI rehabilitation. A workshop on Training in Rehabilitation Medicine was held, which provided opportunities for the participants to obtain information and discuss rehabilitation training options available in Saudi Arabia and other countries (45).

### Iraq

The National Spinal Cord Injuries Centre (formerly IBN Al-Kuff Military SCI Hospital) is the only rehabilitation center in the country. It is located in Baghdad and has a 130-bed capacity. It was established and opened in October 1982. Its Director is Dr. Kaydar M. Al-Chalabi, a member of the ISPRM. Until March 2003, about 3,200 SCI patients underwent a comprehensive rehabilitation program and were followed up regularly. Initially, a Danish medical rehabilitation team worked together with the Iraqi team for 4 years and established the working system. When they left at the end of 1986, the Iraqi rehabilitation team successfully took over the operation. The success rate of this center was similar to other spinal centers. During the last 13 years (1991 to 2003) a lot of difficulties were encountered, including a shortage of medicines, assistive devices, and supplies. However, the center continued operating and a lot of scientific papers from that center were presented in local Arab and international conferences. The hospital academically is linked to the College of Medicine of Baghdad University. Because of the war, the center had stopped operating for a while due to severe damages to the buildings. Rebuilding of the center was completed in 2004 and resumed operations. Despite the difficulties the personnel faced during the imposed sanctions, during and immediately after the last war and the current unstable security status of Iraq, they continue working under the leadership of Dr. Kaydar Al-Chalabi, keeping the PRM specialty in Iraq alive (46).

### Africa (Sub-Saharan)

In this region the rehabilitation services do not yet follow the rehabilitation models of the rest of the world. Although in some countries, such as in South Africa, Zimbabwe, and very recently Ethiopia, the rehabilitation services are better organized and will be mentioned separately. Centers for protection and rehabilitation of torture victims, which often extend their rehabilitation services to nontortured individuals, can be found in the following countries: Democratic Republic of the Congo (Centre Psycho Médical pour la Réhabilitation des Victimes de la Torture—SOPROP, OASIS Centre for Treatment and Rehabilitation of Victims of Torture and Trauma, SAVE

Congo DR), *Cameroon* (Center for Rehabilitation and Abolition of Torture, Trauma Centre Cameroon), *Ethiopia* (Rehabilitation Center for Victims of Torture in Ethiopia), *Kenya* (Independent Medico Legal Unit), *Nigeria* (Consulting Centre for Constitutional Rights and Justice), *Rwanda* (Forum des Activistes Contre la Torture), *Senegal* (Victimes de Violences Rehabilitées, le Centre de Soins du CAPREC), Republic of *South Africa* (The Trauma Centre for Survivors of Violence and Torture), *Sudan* (Amel Center for Treatment and Rehabilitation of Victims of Torture), *Uganda* (African Centre for Treatment and Rehabilitation of Torture Victims), and *Zimbabwe* (AMANI Trust, Mashonaland Programme) (47).

### South Africa

There are several sites that offer medical rehabilitation services. In Johannesburg, within the Barney Morwitz Hospital there is a 21-bed ward for general rehabilitation. The Johannesburg Cardiac Rehabilitation Center and the Hillbrow Acute Hospital Pain Clinic are set up in an interdisciplinary manner utilizing all aspects of rehabilitation; The Acordeck/Tintswald Community Hospital offers a CBR program model called “WITS/Tintswald rehab worker training”. In Cape Town, there is the Grotte Shuur Hospital with a wing devoted to stroke rehabilitation, the Conradic Hospital has an SCI unit with 169 beds; In Port Elisabeth Aurora Hospital, a registered private hospital is dedicated to PMR and subacute care is a collaboration between the QuadPara Association of South Africa and the private sector. Throughout South Africa there are several private RM clinics dealing with all kinds of rehabilitation problems (48,49).

### Zimbabwe

Public and privately owned rehabilitation hospitals, schools, vocational training centers, and associations for and of people with disabilities comprise key rehabilitation service providers. The Zimbabwean Ministry of Labour and Social Welfare (MLSW) provides grants for the vocational training of people with disabilities who are registered with training centers in the country. The Ministry of Health and Child Welfare (MHCW) has rehabilitation units at each of the 15 referral hospitals in the country. It also shares responsibility with the MLSW for rehabilitation services provided at the nine national rehabilitation centers. The MLSW has responsibility over the administration and management of the centers as well as the vocational skills programs, whereas the MHCW runs the hospital within the rehabilitation centers. A majority of the large corporations in industry and commerce have rehabilitation departments for their workers. Organizations for and of people with disabilities are more involved with vocational and psychosocial rehabilitation than with occupational and physiotherapy (50).

### Ethiopia

In collaboration with “Light for the World” (Austria), a CBR program started. The program runs now in six Kebeles (the smallest administrative unit in Ethiopia) in North Gondar: two in the city of Gondar and four in the rural villages of North

Ethiopia. It is focused on giving proper care and follow-up to children who have clubfeet or hydrocephalus, to women who suffer from fistulas after obstructed labor, children who become disabled due to obstructed labor or unsafe and unsuccessful abortions, and to others. The priorities of this program are to educate the patients, the medical providers and convince the Ethiopian community that just as important as saving lives is rehabilitating and adding quality to life. The CBR program is a service program but they also train physiotherapy students. The University aims to produce graduates who are equally willing to work in urban and rural areas. In 2006, the first 80 physiotherapists graduated. This started a new and exciting period in Ethiopia, as the new graduates face a challenge together with other health professionals in developing rehabilitation services in Ethiopia (51).

## ASIA AND OCEANIA

About 60% of the world's population, of which 5% to 10% are disabled, reside in Asia and Oceania (52). The wide variation in culture and economic development within the region has a significant impact upon the breadth and scope of rehabilitation services. In the developed countries of the region, the increasing demand for rehabilitation care is related to the aging population, particularly musculoskeletal disorders and stroke rehabilitation. Nevertheless, most Asian countries are developing countries and have limited health care and welfare service resources. Malnutrition, infectious disease, traffic and work accidents, natural disasters, and even wars continue to play important causative roles for disasters in many Asian countries (53). As a result of limited resources and limited expertise in rehabilitation, a CBR approach has been advocated and practiced in some developing countries in Asia (54–59).

Given the diversity in the practice of medical rehabilitation among the Asian and Oceanic countries, a formal collaboration has not been developed until recently. The ASEAN (West Asian Region) Rehabilitation Medicine Association Congress was established in 1998 and held its first meeting the same year in Thailand. A subsequent meeting was held in 2002 in the Philippines. Between these two meetings, a Millennium Asian Symposium, sponsored by the Japanese Association of Rehabilitation (60), was held in Japan in 2001. At this meeting, representatives from various Asian countries discussed the establishment of an Asian Society of Rehabilitation Medicine. Thereafter, the Korea-Japan Joint Conference on Rehabilitation Medicine was held in Korea in 2002 and Japan in 2004. These joint conferences stimulated the establishment of the Asian Society of Physical and Rehabilitation Medicine. These meetings, coupled with a rapid economic development in some Asian countries, prompted a growing interest to establish a regional society to facilitate the development and promotion of the PRM Specialty. As a result, a regional society, the Asian Oceania Society of Physical and Rehabilitation Medicine (AOSPRM), was officially established in Seoul during the 4th World Congress of ISPRM 2007 after initial task force

meetings that were held in Sao Paulo, Brazil, and Zhuhai, China, in 2005 and 2006, respectively. Hereafter, AOSPRM plans to hold biannual congresses, with the first held in 2008 in Nanjing, China. This first regional conference of the Asian and Oceanic region attracted more than 700 participants from its 19 member countries and included attendees from Europe and North and South America. During the conference, further closer collaboration among the countries in the region in terms of training, research, and exchange was put forward. A decision on a minor amendment of the official name of AOSPRM as “Asia-Oceanian Society of Physical and Rehabilitation Medicine” was also made during the Nanjing conference. The Asia-Oceanian conference is biannual from 2008 onward to promote academic exchange within the region and collaboration with other regions around the world.

As shown in Table 22-8, 19 countries or administrative regions are currently members of this newly established regional society and more countries are expected to join in the near future. Different countries use different designations for PMR. The three most commonly used designations are RM, PMR, and PRM, while RM is the more commonly used term.

Japan and Philippines established academic societies in the 1960s while two thirds of the other countries established their academic societies in 1980 or later. The specialty of PMR is relatively new in this region. Physiatrists number 1% or less of the total number of practicing doctors in most countries (61,62). In some countries the specialty was only established in the last few years, and some are still lacking sufficient physiatrists for the specialty and academic societies to develop.

The degree of maturity of training programs in the specialty of PRM also varies in an analogous fashion to the specialty itself. Within the countries or administrative regions that have well-established training programs, there are also variations in entry into and the years of required PMR training. In some countries, 2 to 3 years of general training in medicine along with passing an entry examination is required before commencing formal PMR training, after which a board certification examination is required for accreditation as a physiatrist. In general, the years spent in core training for PMR varies from 3 to 5 years in most countries that offer training programs (61,62). Features of convergence and divergence of training programs between and within countries occur. For example,

**TABLE 22.8 International PMR: Comparative Data & Characteristics**

Country or Administrative Region	Population (Millions)	PMR Association	Year of Establishment	Number of Physiatrists	PMR Training (Years)	Board Certification Examination	CME/CPD Activities
Australia	21.2	Australasia Faculty of RM <sup>a</sup>	1993	300	2 + 4	Yes	Yes
New Zealand	4.3						
Bangladesh	158.7	Bangladesh Association of PRM	1995	25	3	Yes	n/a

		Thai RM Association	1988				
Vietnam	87.4	Vietnam Rehabilitation Association	1991	1400	3	n/a	n/a

<sup>a</sup> Formerly Australia College of Rehabilitation Medicine 1980–1992.

<sup>b</sup> Previously known as Chinese Society of Physical Therapy 1978–1984.

<sup>c</sup> Formerly Philippine Society of Physical Medicine and Rehabilitation 1960–1973.

n/a, not established yet; PRM, physical and rehabilitation medicine; PMR, physical medicine and rehabilitation; RM, rehabilitation medicine; CME/CPD, Continuous Medical Education/Continuous Professional Development.

Australia and New Zealand share the same academic society and training system while China has a different training program in the mainland from her special administrative region, Hong Kong. Activities for CME or CPD have been established in most countries that have the board certification examination.

In some Asian countries, the practice of PMR has been to some extent influenced by Eastern Medicine. Given the long history of Traditional Chinese Medicine (TCM) or Oriental Medicine in some countries such as China, some components of these systems have been incorporated into the daily practice of PMR. An international survey on stroke rehabilitation showed that in some of the Asian countries, Oriental Medicine techniques such as acupuncture and massage were more commonly used for stroke patients in comparison with countries in other parts of the world (63). This has triggered interest in the “East-meets-West” program whereby medical expertise is exchanged. The other important aspect of providing rehabilitation services to the disabled in some Asian countries has occurred through CBR. However, there have not been any formal training components in terms of CBR within the PMR training programs in any of these countries. This will be one of the important areas of PMR training to develop in the region.

With the advocacy of evidence-based medicine and practice, TCM and Oriental Medicine has opened up areas for research, which will likely lead to evidence for the role of TCM and Oriental Medicine in PMR. Instead of separate practices of Western and Oriental Medicine, a combined approach for a “Universal Medicine” will be an area of interest to develop among the physiatrists in the region. This foreseeable development will likely be brought about by the strengthening of collaboration within the AOSPRM to facilitate PMR specialty training and research in the region. Interregional collaboration such as between AOSPRM and European Society of PMR is also developing. Even though the PMR specialty is relatively immature in the region, it will have a foreseeable bright future through a joint effort within the region and collaboration with other regions.

## INTERNATIONAL EXCHANGE PROGRAMS

International PMR exchange programs exert a powerful force on world health both in practical terms and with respect to humanistic values (64). Pragmatically speaking, global exchange programs can significantly enhance care for international citizens, by altruistically promoting the sharing of information, knowledge, and technical expertise (“teach others and learn from others”) among disparate nations across the globe. Additionally, international PMR exchange programs may broaden research horizons and collaborative vistas, potentially leading to new scientific discoveries. Humanistic projects and global exchange endeavors can unite nations (3).

A series of biennial international interactive workshops: “Building Global Bridges: International PMR Educational Exchange” were conducted in the Czech Republic (2003), Brazil (2005), and Korea (2007) and included representatives from

many of the member nations of the international rehabilitation community. These workshops served as a candid forum for discussion of views and insights about visiting opportunities, educational programs, exchange possibilities, humanitarian initiatives, local rehabilitation resources, and residency curriculum highlights. The historical event included panelists from sample countries, representing the five continents of Africa, America, Australia, Asia, and Europe, who were committed to participating in global physiatric didactic exchange programs. To further the goal of international cooperation and education “across the oceans”, representatives of “developing” and “developed” countries were active participants (65,66).

Promotion of international goodwill through education, faculty-student exchange, and humanitarianism is a noble physiatric goal and is a major objective of the ISPRM Faculty-Student Exchange Committee.

The committee’s activity began in earnest in 2002 when then President John Melvin (United States) and President-elect Haim Ring (Israel) recognized the vital importance of creating an ISPRM outreach arm dedicated to promoting international educational exchange. That year, the Exchange Committee was founded. With the ongoing encouragement and mentorship of the ISPRM Board and leadership including Professor Linamara Batistella and Professor Chang-il Park, the committee has continued to promote international exchange activity among physiatrists internationally. Through its various international humanitarian projects, it has touched the lives of many people with disabilities on a global level.

The ISPRM Faculty-Student Exchange Committee serves as an information resource, international liaison, and active placement service for educational, advocacy, and humanitarian opportunities in PRM, across all continents. The committee facilitates placement of physiatrists in rotations and observerships as well as in rehabilitation-related humanitarian projects based on geography and need.

The committee maintains a Web site [www.isprm-edu.org](http://www.isprm-edu.org) which provides an activity overview as well as a photo album highlighting outcomes and successes. The exchange committee serves a diverse group of rehabilitation professionals and facilitates international placement in educational, research, and humanitarian rotations. Participants in the program represent virtually all stages of education and levels of academic achievement. The core groups served include senior medical students, PMR residents, and attending physiatrists in private practice, PMR academic faculty, and PMR researchers. The committee also supports other nonphysician rehabilitation professionals in obtaining rotational opportunities (Fig. 22-3).

The ISPRM Exchange Committee serves several fundamental roles including facilitating education and research opportunities, coordinating disability advocacy and humanitarian projects as well as other functions shown in Figure 22-4.

Specific objectives include advancing knowledge of RM and techniques, improving quality of care for developed and developing nations, arranging lectures, workshops and seminars, and providing humanitarian assistance during and after times of crisis, for example, tsunamis, hurricanes (67), and cyclones.

**FIGURE 22-3.** ISPRM exchange committee activity groups served.

The committee performs a variety of tasks consistent with its mission and vision. Some of these activities are

1. Handling daily e-mail and postal mail correspondence from rehabilitation physicians interested in additional information about global exchange opportunities
2. Gathering background information about prospective students and visitors (CVs, resumes, letters of reference) and determining areas of interest to ensure an appropriate "match" and a meaningful educational experience
3. Building networks of "exchange partners" and securing participating academic faculty and institutions by sending invitational e-mail queries
4. Monitoring "day-to-day" progress and logistics of actively rotating students, residents, and faculty, especially when those doing rotations spend time in more than one observership during a particular "placement". In this capacity, the chair of the committee can be viewed as a cross between a "camp counselor" and a residency program director
5. Developing preplacement administrative infrastructure documents for the support of placements, e.g., waiver

forms, liability disclaimer documents, and academic institution sign-offs

6. Interfacing with institutional physicians, administrators, as well as governmental officials on matters pertaining to educational and humanitarian exchange opportunities. These activities are conducted in concert with input and guidance from the ISPRM executive leadership
7. Maintaining and updating an outcome focused web-based photo journal and textual narrative which reviews particular placements that the committee has made in addition to tracking global exchange activities
8. Submission of articles and updates pertaining to committee activity to "News & Views" and other academic publications
9. The activities of the committee are conducted in a team fashion with individual members of the committee providing input, direction, and collaborative assistance
10. Interfacing with other ISPRM members (including past and present leadership) to apprise them of committee activity and to seek their input
11. Submission of an annual written report to the ISPRM Board as well as meeting regularly with the plenary ISPRM Board to provide a committee report

The process by which physiatrists are placed in global opportunities is represented in Figure 22-5.

The committee remains committed to promoting international placements for traveling physiatrists and welcomes the active help and input of potential host institutions abroad.

The exchange committee proposes the establishment of an ISPRM recognized "global faculty," comprised of physiatrists who have hosted visiting exchange students and physicians. International institutions and physicians interested in participating may contact the committee, the Chair of the Committee, Mark Young: [markyoung123@gmail.com](mailto:markyoung123@gmail.com) or through the Web site: [www.isprm-edu.org](http://www.isprm-edu.org).

**FIGURE 22-4.** ISPRM exchange committee.

**FIGURE 22-5.** Work process of ISPRM exchange committee.

## THE INTERNATIONAL REHABILITATION ORGANIZATIONS

As time has elapsed since the beginning of the modern era, colleagues from different parts of the world have looked to come closer and organize themselves into international organizations, meetings, courses, and the like. The International Federation of Physical Medicine was created in 1950 as a federation of existing national societies subsequently changing its name to the IFPMR. The first international meeting took place in 1952 in London (United Kingdom). Later congresses took place in 1956 (Copenhagen), 1960 (Washington), 1964 (Paris), 1968 (Montreal), 1972 (Barcelona), 1976 (Rio de Janeiro), 1980 (Stockholm), 1984 (Jerusalem), 1988 (Toronto), 1992 (Dresden), and 1995 (Sydney).

In 1968, the IRMA was created in order to provide a professional and social framework on an individual basis to those rehabilitation professionals who were not part of a national society. The first congress took place in 1970 in Milan and Turin (Italy). The second IRMA congress took place in 1974 in Mexico City (Mexico), then in 1978 in Basel (Switzerland), in 1982 in San Juan (Puerto Rico), in 1986 in Manila (Philippines), in 1990 in Madrid (Spain), in 1994 in Washington, DC (the United States), and in 1997 in Kyoto (Japan). The last IRMA's congress took place in 1997 in Kyoto (Japan) and the last IFPMR's congress took place in 1999 in Washington, DC (the United States). Since both organizations shared many common officials on their respective boards, they merged to become the ISPRM—[www.isprm.org](http://www.isprm.org), currently based in Assenede (Belgium).

The first ISPRM meeting took place in 2001 in Amsterdam (Holland) with 1,200 participants, the second in 2003 in Prague (Czech Republic) instead of the original

designated place Jerusalem (Israel) due to local conditions at the time with 1,400 participants (95% of active participants), the third one in 2005 in Sao Paulo (Brazil) with 1,800 participants, and the fourth one in 2007 in Seoul (South Korea) with 2,400 participants from 75 countries. The number of participants, as well scientific presentations, steadily increased from one congress to the next. This gave the opportunity to colleagues in different parts of the world to participate in this unique event. The scope of the presentations also changed over time (68) with the incorporation of advanced technologies in rehabilitation (robotics, virtual reality, functional electrical stimulation) as well the new WHO-ICF, along with the more classical topics.

The last ISPRM congress was held in 2009 in Istanbul (Turkey). Future congresses will take place in 2011 in San Juan (Puerto Rico) and in 2013 in Beijing (China). Besides the pure international organization congresses, an increasing number of regional or continental rehabilitation organizations are conducting meetings, with a broad professional scope, and most of them are described in the respective sub-chapters: AMLAR in Latin America, the ESPRM and the EFRR in Europe, the MFPRM in the Mediterranean region, and the most recent being the AOSPRM composed of 17 national organizations that held its first meeting in Nanjing (China) in May 2008. Additional regional meetings are the so-called “Middle East Chapter” for Arab countries colleagues, the Trans-Pyrenean Congress (NE Spain and SW France) and the Baltic Rehabilitation congress for countries around the Baltic Sea, having its last meeting in Riga (Estonia) in 2008. Other societies deal with more specific aspects (movement analysis, etc.).

It can be safely said that these regional congresses serve as a means of integration at the regional level (“regionalism”) and the basis for the strengthening of the world ones.

## THE INTERNATIONAL REHABILITATION JOURNALS—PUBLISHING IN PRM JOURNALS

For many years, rehabilitation professionals have strived to express their views, work, and scientific production in scientific PRM journals. Some of them have done and still do so in national and regional journals in their own languages. It is difficult to accurately determine the number of these journals on a world level but there are surely several dozens. Over 33 indexed journals appeared doing a computer search for the term rehabilitation journals in English. About two third of these journals are published in the United States and the rest were mainly in the United Kingdom. In addition, there are PRM journals published in English by publishing houses based in Holland, Sweden, and Italy. The declared main topic is either wide (general rehabilitation), or involve specific topics such as assistive technology, research in rehabilitation, bioengineering, nursing, psychological/psychiatric, occupational therapy, rehab management and counseling, etc. Other journals focus on a main or defined pathology: stroke, brain injury/head trauma, genera; neurological, spinal cord, prosthetic and orthotics, cardiopulmonary, back and musculoskeletal, burn care and rehabilitation, or cancer rehabilitation. Some are devoted to specific patient ages with their related pathologies such as pediatric or geriatric. The highest Impact Factor (determined by the number of citations and the general number of publications over a given period of time—usually 1 year) is held by the following general international rehabilitation journals in English: *Neurorehabilitation and Neural Repair*, *Journal of Rehabilitation Medicine*, *Archives of Physical Medicine and Rehabilitation*, *Clinical Rehabilitation*, *American Journal of Physical Medicine and Rehabilitation*, *Brain injury*, *Disability and Rehabilitation*, *International Journal of Rehabilitation Research*, among others.

In 2009, the AAPM&R initiated a new publication: *The Journal of Injury, Function and Rehabilitation* with a clinical emphasis. The issue of publishing in PRM journals, with the problems inherent to the submission, review (peer-review), and acceptance/refusal decision processes, were first discussed in a special session titled “Meet the Editor,” in the 2nd ISPRM World Congress in Prague (transferred from Jerusalem). This resulted in a joint paper by participants and chair, published in the congress proceedings (69) and at the 4th World Congress in Seoul in 2007. With a record attendance for that congress, participants generated a peer-reviewed article published simultaneously in three different first-line journals (70): *The American Journal of Physical Medicine and Rehabilitation* (USA), *The Journal of Rehabilitation Medicine* (Sweden), and *the Disability and Rehabilitation Journal* (UK). Topics discussed in the session included the reasons for publishing in peer-review journals, important considerations in submitting a manuscript, the peer-review process, the effect of electronic publishing—which leads to shorter publication times, the opportunity to preview papers, and more open access to journals. The discussions concluded that the field of PRM will

continue to expand, with an audience having a broader range of scientific and clinical interests. Another important conclusion was that the ICF may be increasingly used as a framework in reporting. Intermediate meetings of this kind were also held in the 6th and 7th Mediterranean PRM Congresses held in Vilamoura (Portugal) in 2006 and Portorose (Slovenia) in 2008 respectively, bringing the discussion close to potential writers and reviewers in the region.

## CONCLUSION

*There are some words whose meanings are so universally accepted that definition is unwarranted and might be considered pedantic by some. Physical medicine is such a term to some but not to others, for most specialists in physical medicine have their own idea of its meaning. But there are as many definitions as there are countries, and within some countries there are many definitions, for this is a specialty that stems from many older specialties, each of which has its own national and international history.*

Sidney Licht, 1960

From the historical perspective (71,72), there is no doubt that RM has come a long way since its inception. Although differences still persist among regions and systems, there is no doubt that significant and rapid changes occur in parallel across all the regions in the world, developed and developing countries alike. Regional and world congresses, the international PRM journals, and the ISPRM International Exchange Program have made great contributions to an international harmonization in residency and teaching programs, the understanding and building of common concepts and terms, the establishment of new rehabilitation systems, and the development of strategic plans to strengthen the stability of those systems in jeopardy.

Research in rehabilitation is thriving and the quality of the research programs as well their scope is dramatically improving, including animal experimental studies (73). One of the most salient features of the last years is the impressive recruitment, in number and mainly in quality of a cadre of active members that, whether they fill some formal position or not, are increasingly devoting themselves to the regional and international organizations. This has brought about a dramatic upgrade of standards of work and activities. By now a kind of “international carrier” has been created in the rehabilitation realm. Above all, if to judge by the different regional reports, there is a bright future for RM. The profession is closing the gaps among regions and is actively becoming global (2). It is the dawn of a new day.

## ACKNOWLEDGMENT

Special thanks to Jeff Shames (Israel), for his help in all the stages of chapter preparation. The authors are grateful to the following people for their invaluable contribution in

the preparation of the chapter: Graciela Borelli (Uruguay), Tai Ryoan Han (Korea), Jianan Li (China), Juan Lacuague (Uruguay), Rodney Li Pi Shan (Canada), Bryan O'Young (the United States), Mauro Zampolini (Italy).

### Memorial:

The coauthors of this chapter wish to acknowledge posthumously the significant contributions of the late Professor Haim Ring in the initial iteration of this chapter. Professor Ring's leadership skills and academic contributions to International Physiatry will always be remembered and treasured.

PART

# Major Conditions

# Stroke Rehabilitation

## INTRODUCTION

Stroke has been recognized since antiquity, and it remains a major cause of disability today. In this chapter, we review the causes, mechanisms, and symptoms of stroke, including a discussion of common stroke syndromes. We then address the evaluation of stroke cause and strategies to prevent recurrent stroke, an area that requires full integration into the rehabilitative phase of care. An overview of acute stroke management is provided, which segues into the various stages of rehabilitation after a stroke. The expanding emphasis on facilitating neurological recovery after stroke is highlighted as it has become a major focus of rehabilitation research since the prior edition of this book was published, and this shift is expected to continue. Lastly, we discuss some of the long-term sequelae of stroke and their management.

## DEFINITION

A stroke is the sudden occurrence of permanent damage to an area of the brain caused by a blocked blood vessel or bleeding within the brain. Other causes of focal brain damage, such as traumatic injury to the brain, demyelinating lesions, brain tumors, brain abscesses, and others, can produce strokelike symptoms but are not included in this definition.

Strokes can be divided into two major categories: ischemic, generally caused by a vascular occlusion, and hemorrhagic, caused by bleeding within the parenchyma of the brain. Some classify nonparenchymal hemorrhage, such as subarachnoid hemorrhage (SAH) due to a ruptured intracranial aneurysm, as a form of hemorrhagic stroke as well.

A significant number of people who sustain a stroke do not reach medical attention due to a lack of symptoms or the failure to recognize the symptoms as requiring medical attention. (It is estimated that 28% of individuals aged 70 to 74 have had a silent cerebral infarction) (1). The most common symptom of stroke is focal weakness, though stroke can produce a wide range of symptoms such as sensory loss, speech and language disturbance, visual loss, etc. The resultant neurological deficits are generally referred to as *impairments*, which may or may not result in functional limitations often characterized as *disability*.

The objectives of stroke rehabilitation are to achieve a maximum level of functional independence; facilitate neurological recovery, minimize disability; successfully reintegrate back into

home, family, and community; and reestablish a meaningful and gratifying life. Education of the stroke survivor and his or her family regarding secondary stroke prevention, including risk factor modification, and compliance with medical therapy for stroke prevention are responsibilities shared by the rehabilitation team. These goals are accomplished through exercise and other treatments to facilitate recovery and reduce impairments; functional training to compensate for residual impairments; and use of assistive devices, such as braces or wheelchair, to substitute for lost function. Successful rehabilitation also requires management of the many psychosocial issues that surround integration of the patient back to home and community.

## EPIDEMIOLOGY

Each year approximately 780,000 Americans suffer a stroke, of which 600,000 are an initial event and the remainder are recurrent strokes (1). While the number of strokes in the United States continues to rise as a result of the aging of the population, their incidence has been stable in recent years at about 158 per 100,000 population. This contrasts with the death rate from stroke, which has fallen 24% from 1994 to 2004 (with a reduction in the total number of stroke deaths of 6.8% [due to population growth and aging of the population]). Stroke remains the third leading cause of death in the United States, after heart disease and cancer. Incidence is age related, being uncommon before age 50 but doubling each decade after age 55. Stroke is more common among men than among women in younger cohorts, but more common among women for individuals over age 85 (1).

## RISK FACTORS AND PREVENTION

Prevention remains of critical importance in reducing the burden of morbidity and mortality from stroke. Risk factors for ischemic stroke have been identified and can be separated into two categories: those that are potentially modifiable and those that are not modifiable. The latter includes age, race/ethnicity, sex, and family history, whereas the potentially modifiable risk factors include hypertension, smoking, atrial fibrillation, diabetes, diet, obesity, sedentary lifestyle, and hyperlipidemia.

Risk factors for hemorrhagic stroke have also been identified, and while primary stroke prevention efforts generally focus

on the risk factors for ischemic stroke, secondary prevention efforts for individuals who have already sustained a hemorrhagic stroke should include education with a particular focus on treating hypertension, refraining from excessive alcohol consumption, and avoiding the use of anticoagulant medications.

The following discussion focuses on potentially modifiable risk factors for ischemic stroke, listed in Table 23-1.

### Modifiable Risk Factors in Asymptomatic Individuals

**Hypertension** is the most important risk factor. The degree of risk increases with elevation and becomes particularly strong with levels higher than 160/95 mm Hg. Systolic hypertension and high mean arterial pressure represent parallel risks. In the Framingham study, a sevenfold increased risk of cerebral infarction was observed in patients who were hypertensive (2). Hypertension increases the risk of thrombotic, lacunar, and hemorrhagic stroke and increases the likelihood of SAH. Successful long-term treatment of hypertension greatly reduces the risk of these events, even after a prior stroke (3). The hypothesis that angiotensin receptor blockers might provide specific stroke prevention benefits beyond their blood pressure lowering effects has not been borne out (4).

Because of concerns regarding maintaining flow distal to critical cerebrovascular stenoses, aggressive management of hypertension immediately after stroke should be avoided. Studies have shown that abrupt reductions in blood pressure within the first 24 hours after stroke are associated with poorer outcomes (5). Clinicians typically aim to gradually bring blood pressure into the normotensive range over a period of weeks after a stroke, though little data exist to guide this practice.

**Heart disease** is an important risk factor for stroke. To some degree, this reflects the shared risk factors and pathophysiology of stroke and heart disease: hypertension and atherosclerosis. The risk of stroke is doubled in individuals who have coronary artery disease (6), and coronary artery disease accounts for the majority of subsequent deaths among stroke survivors. Atrial fibrillation and valvular heart disease increase the risk of cerebral infarction because both may cause cerebral emboli. In patients with chronic, stable atrial fibrillation, the risk of stroke is increased fivefold (7). When atrial fibrillation is a

manifestation of rheumatic heart disease, the risk of embolic stroke is increased up to 17 times normal (7). Prevention of embolic stroke in these patients is best achieved by long-term anticoagulation with warfarin. Treatment carries the danger of intracranial hemorrhage, especially in elderly individuals and in those with impaired balance and who are likely to fall. When the risk of hemorrhage appears to be high, aspirin in a dose of 325 mg daily may be used as an alternative to warfarin in patients with nonvalvular atrial fibrillation, although aspirin is much less effective than warfarin in preventing embolism. Younger patients (below age 75) without valvular heart disease and who lack other risk factors (e.g., hypertension, diabetes, left ventricular hypertrophy, history of TIA or stroke) are at low risk for stroke and may be treated with aspirin rather than with warfarin (8).

**Diabetes**, as an independent risk factor, doubles the risk of stroke. While achieving good glycemic control is advised for all diabetic patients, studies have not shown a clear relationship between glycemic control and stroke risk (9,10).

**Smoking** has been shown to increase the risk of both ischemic stroke and SAH, with greater amounts of smoking carrying greater risk. Individuals who discontinue smoking have substantial reductions in stroke risk, approximating that of nonsmokers after several years (11). Counseling regarding smoking cessation is an essential component of programs to reduce the risk of recurrent stroke.

**Hyperlipidemia** increases the risk for stroke to a small extent. Treatment with cholesterol-lowering medications other than “statins” has not been found beneficial in reducing the risk of stroke. Conversely, treatment with statin medications has been found to reduce the risk of stroke, in individuals with or without hyperlipidemia (12), raising the possibility that the benefits of statins in stroke prevention may not be related solely to their lipid-lowering effects. Thus, treatment with statins is indicated for primary stroke prevention in patients with coronary heart disease or symptomatic atherosclerotic disease with low-density lipoprotein (LDL) cholesterol levels of 100 mg/dL or greater. In individuals at very high risk for stroke with multiple risk factors, the threshold for treatment is an LDL of 70 mg/dL (13).

**Homocysteine:** Elevated homocysteine have been found to be associated with a higher risk of ischemic stroke. While homocysteine levels can be lowered with supplementary vitamins (folate, vitamins B6 and B12), treatment has not been found to reduce stroke risk (14). Given the low cost and minimal risk of vitamin treatment to reduce homocysteine levels, the current recommendation is that such treatment is “reasonable” despite the lack of evidence of efficacy (15).

**C-reactive protein:** C-reactive protein (CRP) levels have been shown to correlate with risk of cardiovascular disease, including stroke, as have elevated fibrinogen levels. A recent study found that treating individuals with elevated CRP with statins reduced major cardiovascular events, despite normal lipid levels prior to treatment (16). While the role of testing CRP levels to guide stroke prevention remains a subject of debate, it may prove a useful adjunct to other tools for assessing risk.

### Risk Factors for Recurrent Stroke

The probability of stroke recurrence is highest early after a stroke. For survivors of an initial stroke, the annual risk of a second stroke is approximately 5%, with a 5-year cumulative risk of recurrence around 25% (17,18), although it may be as high as 42% (17). Risk factors for initial stroke also increase the risk of recurrence, especially hypertension, heart disease, and diabetes mellitus (19,20). Heavy alcohol consumption is also a risk factor for recurrent stroke.

Mortality after stroke is high, with between 32% and 58% of initial survivors dead within 5 years after a first stroke, with survival varying based on age, sex, and race (1). Leonberg and Elliott (19) were able to achieve 16% reduction in stroke recurrence rate by an energetic and sustained program of control of multiple risk factors. Therefore, efforts should be made to reduce risk of recurrent stroke and mortality by controlling risk factors.

### Types of Strokes

#### Transient Ischemic Attacks

Transient ischemic attacks (TIAs) have historically been defined as a strokelike event that completely resolves within 24 hours. The symptoms of a TIA begin abruptly and may persist for only a few seconds or minutes, followed by apparent full resolution. Despite the fact that TIAs are (by definition) associated with complete resolution of symptoms, a substantial percentage of diffusion-weighted MRIs in patients with TIA will show small acute infarcts corresponding to the individual's symptoms (21). TIAs are not trivial events and require a thorough investigation. Those TIAs associated with MRI evidence of tissue damage carry a particularly high risk of further vascular events (22). In the first month after onset of TIAs, 4% to 8% of patients will develop a completed stroke, and the risk is 30% in the next 5 years (23,24). Generally, stroke prevention in patients with TIAs includes the use of an antiplatelet drug, such as aspirin (24).

### Cerebral Thrombosis

Thrombosis of the large extracranial and intracranial vessels as the result of atherosclerotic cerebrovascular disease accounts for approximately 30% of all cases of stroke (Table 23-2) (20). Atherosclerotic plaques are particularly prominent in the large vessels of the neck and at the base of the brain. Sudden occlusion of one of these large vessels, in the absence of good collateral circulation, usually results in a large brain infarction. Risk factors for atherosclerosis include hypertension, smoking, diabetes, and hyperlipidemia. In some cases, the gradual progressive stenosis of a major blood vessel provides sufficient time for collateral circulation to develop, and complete occlusion may be asymptomatic or produce fewer effects than might otherwise be expected.

Unlike embolic strokes, which tend to have an abrupt onset, atherothrombotic strokes often begin more subtly, and affected individuals may only become aware that they have weakness or other impairment when they attempt to walk or

**TABLE 23.2 Causes of Stroke**

get out of bed. The extent of the clinical deficit usually worsens over some hours or sometimes days, followed by stabilization and then gradual improvement.

### Cerebral Embolism

Embolism is responsible for about 30% of all cases of stroke. Emboli may arise from thrombi within the heart or on the heart valves, from paradoxical embolism, or from an ulcerated atherosclerotic plaque within an extracranial artery (Table 23-3). Cardiogenic embolism may occur from thrombus formation at the site of a recent myocardial infarction, an area of myocardial hypokinesis, within the left atrium in patients with atrial fibrillation, or on diseased or prosthetic valves. Paradoxical embolism results from a deep venous thrombosis in the pelvis or leg that embolizes into the right side of heart, then passes through a patent foramen ovale into the left atrium, and ultimately to the cerebral circulation.

Cerebral embolism presents with an abrupt onset that is due to sudden loss of arterial perfusion to a focal area of the brain. The blood flow and anatomy of the cerebral circulation favor passage of an embolism into the middle cerebral artery territory, though any vascular territory may be affected. Many emboli are friable and may break into smaller pieces as they travel through the cerebral circulation, resulting in multiple smaller infarcts affecting several distal branches of the main vessel.

The initial clinical deficit may change rapidly. If the embolus undergoes lysis and fragmentation, the neurologic

signs may fade rapidly. While treatment with anticoagulants is appropriate for long-term secondary prevention of recurrent stroke, immediate anticoagulation with heparin has been found to increase the risk of symptomatic hemorrhagic conversion (25). For this reason, anticoagulation therapy is frequently delayed from the acute onset for up to 2 weeks in individuals with large cardioembolic infarctions.

### Lacunar Stroke

Lacunar lesions constitute approximately 20% of all strokes and are small, circumscribed lesions, at most 1.5 cm in diameter resulting from occlusions in the deep penetrating branches of the large vessels that perfuse the subcortical structures, including internal capsule, basal ganglia, thalamus, and brainstem. Small lacunar infarcts may produce major neurologic deficits if they occur in key regions but generally cause more minor symptoms than large vessel infarcts and may in fact be asymptomatic. Lacunar strokes are highly associated with hypertension and may result from either microatheroma or lipohyalinosis.

### Cerebral Hemorrhage

Intracerebral hemorrhage accounts for approximately 11% of all cases of stroke. The most common cause of cerebral hemorrhage is hypertension, and intracerebral hypertensive hemorrhage most commonly occurs at the site of small, deep, penetrating arteries. It is thought that hemorrhage occurs through rupture of microaneurysms (Charcot-Bouchard aneurysms) that develop in these vessels in hypertensive patients. The majority of lesions occur in the putamen or thalamus, and in about 10% of patients, the spontaneous hemorrhage occurs in the cerebellum.

Cerebral amyloid angiopathy is another important cause of cerebral hemorrhage, representing 5% to 20% of cases. It is most common after age 65, although may occasionally affect individuals as early as age 45. Hemorrhages tend to be lobar rather than deep, and there is usually evidence of hemosiderin deposition on MRI imaging indicative of prior microhemorrhages at the time of initial clinical presentation. No specific treatments are yet available, aside from avoidance of medications that may predispose to bleeding and appropriate control of hypertension if present.

The clinical onset of the hemorrhage is often dramatic, with severe headache and rapidly progressive neurologic deficits. In patients with larger hemorrhages, consciousness becomes progressively impaired leading to coma. Brain displacement from the hematoma and cerebral edema may give rise to transtentorial herniation and death, generally within the first few days poststroke. While cerebral hemorrhage is associated with a higher mortality rate than infarction, there is some evidence that the neurologic deficit from a hemorrhage may recover to a greater degree than a comparable initial deficit from an infarction (26).

Intracerebral hemorrhages have been demonstrated to continue to expand after initial presentation in a substantial portion of patients. A recent trial of recombinant activated

factor VII reduced the growth of the hematomas but failed to show any improvement in functional status or reduction in mortality (27).

Intracerebral hemorrhage is a well-recognized complication of anticoagulant therapy and may occur spontaneously or after minor trauma. For patients on warfarin, the risk is related to the degree of elevation of the INR. In one study, the adjusted odds ratio for sustaining an intracranial hemorrhage was 4.6 for INRs in the range of 3.5 to 3.9 (compared with individuals with INRs between 2.0 and 3.0) and increased to 8.8 for INRs above 4.0 (28).

Other causes of intracerebral hemorrhage include trauma, vasculitis, and bleeding into a tumor. Patients with a bleeding diathesis—for example, thrombocytopenia or coagulation disorders—may develop an intracranial hemorrhage.

Patients with acute cerebellar hemorrhages typically develop a sudden headache and inability to stand, along with nausea, vomiting, and vertigo. With large posterior fossa lesions, the hematoma and edema may occlude the fourth ventricle, causing acute hydrocephalus. Urgent decompression with evacuation of the hematoma can be lifesaving. Patients who survive surgical evacuation of a cerebellar hemorrhage, or who have a less severe lesion, usually make a good functional recovery, as do patients with cerebellar infarcts (29).

### Subarachnoid Hemorrhage

In about 7% of all stroke patients, the lesion is an SAH, usually resulting from rupture of an arterial aneurysm at the base of the brain with bleeding into the subarachnoid space. Aneurysms develop from small defects in the wall of the arteries and slowly increase in size. The risk of rupture rises as the size of the aneurysm increases, and for this reason, intervention is generally advised for asymptomatic aneurysms greater than 10 mm in diameter (30). Major rupture of an aneurysm may be preceded by headache from a small bleed or by localized cranial nerve lesions caused by direct pressure by the expanding aneurysm. When rupture occurs, the clinical onset is usually dramatically abrupt. There is severe headache followed by vomiting and signs of meningeal irritation. Focal signs are usually not observed initially but may develop as a result of associated intracerebral bleeding or cerebral infarction occurring as a complication of arterial vasospasm. Coma frequently occurs, and as many as one third of patients may die acutely. Rebleeding is very common, and therefore, early surgical/invasive radiological intervention has become routine, with the objective of obliterating the aneurysm to prevent recurrent hemorrhage. Blood in the subarachnoid space may cause arterial vasospasm, leading to localized areas of cerebral infarction with associated focal neurologic deficits. Nimodipine is routinely administered after SAH to reduce the likelihood and/or severity of vasospasm. Hydrocephalus may develop immediately after SAH due to obstruction of the ventricular system from intraventricular hemorrhage, or as a later complication several weeks after the acute event as a result of arachnoiditis from blood in the CSF.

Obliteration of aneurysms may be performed surgically, by clipping the neck of the aneurysm or by the use of detachable coils placed through an angiographic approach to thrombose the aneurysm.

SAH may also result from bleeding from an arteriovenous malformation (AVM), which is a tangle of dilated vessels found on the surface of the brain or within the brain parenchyma. These lesions are congenital abnormalities and tend to bleed in childhood or young adulthood. In about half the cases, the hemorrhage is the first clinical indication of the lesion. In approximately one third of patients, the AVM presents as a seizure disorder or with chronic headaches. In most patients, the lesions eventually bleed. Most patients survive a single hemorrhagic event. The rate of rebleeding is about 6% in the first year and 2% to 3% per year thereafter. Treatment options include surgical excision of the AVM, proton beam therapy, or neurovascular ablation through embolization.

### Stroke Syndromes

The relatively predictable anatomy of the brain's vascular supply, localization of particular functions to certain areas of the brain, and the predilection of stroke for certain vascular territories result in a number of commonly occurring ischemic stroke syndromes. These stroke syndromes can be recognized when they occur and assist in localization of the stroke lesion as well as in predicting functional outcome. While a myriad of stroke syndromes have been described, we discuss only a few of the most common ones in this chapter.

#### Internal Carotid Artery Syndrome

The clinical consequences of complete occlusion of an internal carotid artery vary from no observable deficit to catastrophic. In cases where there is good collateral circulation, no neurological consequences may occur with carotid occlusion. By contrast, massive cerebral infarction in the distribution of the anterior and middle cerebral arteries may present with rapid obtundation, with dense contralateral motor and sensory deficits. In some cases (particularly in younger people), severe cerebral edema may lead to transtentorial herniation and death. In such cases, decompression of the swollen brain with craniectomy may be lifesaving.

Less extensive infarctions result in partial or total lesions in the distribution of the middle cerebral artery. The anterior cerebral circulation may be preserved through flow from the opposite side via the anterior communicating artery.

#### Middle Cerebral Artery Syndromes

The internal carotid artery divides into the middle and anterior cerebral arteries. The middle cerebral artery supplies the lateral aspect of the frontal, parietal, and temporal lobes and the underlying corona radiata, extending as deep as the putamen and the posterior limb of the internal capsule. As the main stem of the middle cerebral artery passes out through the Sylvian fissure, it gives rise to a series of small branches called lenticulostriate arteries, which penetrate deeply into the subcortical portion of the brain and perfuse the basal ganglia

and internal capsule. At the lateral surface of the hemisphere, the middle cerebral artery divides into upper and lower divisions, which perfuse the lateral surface of the hemisphere. When the middle cerebral artery is occluded at its origin, a large cerebral infarction develops involving all the structures mentioned above. Because of the cerebral edema that usually accompanies such a large lesion with brain displacement, the patient frequently shows depressed consciousness, with head and eyes deviated to the side of the lesion, with contralateral hemiplegia, decreased sensation, and homonymous hemianopia. If the dominant hemisphere is involved, aphasia is usually present, which may be severe if the entire territory of the MCA is infarcted. As the patient's mental status improves, other features become evident, namely dysphagia, contralateral hemianopia, and, in patients with nondominant hemisphere lesions, perceptual deficits and neglect. Patients who survive the acute lesion regain control of head and eye movements, and normal level of consciousness is restored. However, severe deficits involving motor, visuospatial, and language function usually persist.

Occlusion of the middle cerebral artery branches, except for the lenticulostriate, is almost always embolic in origin, and the associated infarctions are smaller and more peripherally located than those seen after occlusion of the MCA trunk. The superior division of the middle cerebral artery supplies the Rolandic and pre-Rolandic areas, and an infarction in this territory will result in a dense sensory-motor deficit on the contralateral face, arm, and leg, with less involvement of the leg. As recovery occurs, the patient is usually able to walk with a spastic, hemiparetic gait. Little recovery occurs in motor function of the arm. If the left hemisphere is involved, there is usually severe aphasia initially with eventual improvement in comprehension, although an expressive aphasia is likely to persist. Small focal infarctions from occlusions of branches of the superior division will produce more limited deficits such as pure motor weakness of the contralateral arm and face, apraxia, or expressive aphasia.

The inferior division of the middle cerebral artery supplies the parietal and temporal lobes, and lesions on the left side result in severe involvement of language comprehension. The optic radiation is usually involved, resulting in partial or complete contralateral homonymous hemianopia. Lesions affecting the right hemisphere often result in neglect of the left side of the body. Initially, the patient may completely ignore the affected side and even assert that his left upper extremity belongs to someone else. Such severe neglect often gradually improves but may be followed by a variety of persisting impairments such as deficits in attention, constructional apraxia, dressing apraxia, perceptual deficits, and aprosodia.

Several characteristic and rather common syndromes have been described when lacunar strokes occur in the distribution of the lenticulostriate branches of the middle cerebral artery. Among the most common is a lesion in the internal capsule causing a pure motor hemiplegia. An anterior lesion in the internal capsule may cause dysarthria with hand clumsiness, and a lesion of the thalamus or adjacent internal capsule causes

a contralateral sensory loss with or without weakness. The neurologic deficits in these lesions often show early and progressive recovery with good ultimate outcome.

### Anterior Cerebral Artery Syndromes

Branches of the anterior cerebral arteries supply the median and paramedian regions of the frontal cortex and the strip of the lateral surface of the hemisphere along its superior border. There are deep penetrating branches that supply the head of the caudate nucleus and the anterior limb of the internal capsule. Occlusions of the anterior cerebral artery are not common, but when they occur, there is contralateral hemiparesis with relative sparing of the hand and face and greater weakness of the leg. There is associated sensory loss of the leg and foot. Lesions affecting the left side may produce a transcortical motor aphasia characterized by diminution of spontaneous speech but preserved ability to repeat words. A grasp reflex is often present along with a sucking reflex and paratonic rigidity (also known as *gegenhalten*—muscle hypertonia presenting as an involuntary variable resistance during passive movement of a limb). Urinary incontinence is common. Large lesions of the frontal cortex often produce behavioral changes, such as lack of spontaneity, distractibility, and tendency to perseverate. Affected individuals may have diminished reasoning ability. Bilateral anterior cerebral artery infarctions may cause severe abulia (lack of initiation).

### Vertebrobasilar Syndromes

The two vertebral arteries join at the junction of the medulla and pons to form the basilar artery. Together, the vertebral and basilar arteries supply the brainstem by paramedian and short circumferential branches and supply the cerebellum by long circumferential branches. The basilar artery terminates by bifurcating at the upper midbrain level to form the two posterior cerebral arteries. The posterior communicating arteries connect the middle to the posterior cerebral arteries, completing the circle of Willis.

Some general clinical features of lesions in the vertebrobasilar system should be noted. In contrast to lesions in the hemispheres, which are unilateral, lesions involving the pons and medulla often cross the midline and produce bilateral symptoms. When motor impairments are present, they are often bilateral, with asymmetric corticospinal signs, and they are frequently accompanied by cerebellar signs. Cranial nerve lesions are very frequent and occur ipsilateral to the main lesion. There may be dissociated sensory loss (involvement of the spinothalamic pathway with preservation of the dorsal column pathway or vice versa), dysarthria, dysphagia, disequilibrium and vertigo, and Horner's syndrome. Of particular note is absence of cortical deficits, such as aphasia and cognitive impairments. Visual field loss and visuospatial deficits may occur if the posterior cerebral artery is involved, but not with brainstem lesions. Identification of a specific cranial nerve deficit allows precise anatomic localization of the lesion.

Lacunar infarcts are common in the vertebrobasilar distribution, arising from occlusion of small penetrating branches

of the basilar artery or posterior cerebral artery. In contrast to cerebral lacunes, most brainstem lacunes are symptomatic. There is a variety of characteristic brainstem syndromes associated with lesions at various levels in the brainstem. Pontine lacunar infarcts frequently result in a pure motor hemiparesis. The reader is referred to neurologic texts for a comprehensive discussion of these lesions. Several brainstem syndromes are relatively common among patients referred for rehabilitation, and these are described in some detail.

The *lateral medullary syndrome* (Wallenberg's syndrome) is produced by an infarction in the lateral wedge of the medulla. It may occur as an occlusion of the vertebral artery or the posterior inferior cerebellar artery. The clinical features of this syndrome, along with the corresponding anatomic structures involved, are impairment of contralateral pain and temperature (spinothalamic tract); ipsilateral Horner's syndrome consisting of miosis, ptosis, and decreased facial sweating (descending sympathetic tract); dysphagia, dysarthria, and dysphonia (ipsilateral paralysis of the palate and vocal cords); nystagmus, vertigo, nausea, and vomiting (vestibular nucleus); ipsilateral limb ataxia (spinocerebellar fibers); and ipsilateral impaired sensation of the face (sensory nucleus of the fifth nerve). Patients with this syndrome are frequently quite disabled initially because of vertigo, disequilibrium, and ataxia, but they often make a good functional recovery.

Occlusion of the basilar artery may result in severe deficits with complete motor and sensory loss and cranial nerve signs from which patients do not recover. Patients are often comatose. *Locked-in syndrome* is an uncommon but devastating stroke syndrome involving the brainstem. The infarction in such cases affects the upper ventral pons, involving the bilateral corticospinal and corticobulbar pathways but sparing the reticular activating system and ascending sensory pathways. Patients have normal sensation and can see and hear but are unable to move or speak. Blinking and upward gaze are preserved, which provides a very limited but usable means for communication. The patient is alert and fully oriented. Some patients do not survive, and those who do are severely disabled and dependent. Slow improvement and partial recovery may occur in this group of patients, justifying appropriate levels of rehabilitation intervention.

Focal infarctions may occur in the midbrain and affect the descending corticospinal pathway, sometimes also involving the third cranial nerve nucleus (Weber's syndrome), resulting in ipsilateral third nerve palsy and paralysis of the contralateral arm and leg.

Eye movement abnormalities are seen in a variety of brainstem stroke syndromes due to the location of the nuclei for these cranial nerves in the midbrain (third and fourth cranial nerves) and pons (sixth nerve) and their interconnections.

The posterior cerebral artery perfuses the thalamus through perforating arteries, as well as the temporal and occipital lobes with their subcortical structures, including the optic radiation. An occipital lobe infarction will cause a partial or complete contralateral hemianopia, and when these visual deficits involve the dominant hemisphere, there may be associated

difficulty in reading or in naming objects. When the thalamus is involved, there is contralateral hemisensory loss. A lesion involving the thalamus may cause a syndrome characterized by contralateral hemianesthesia and central pain, although only about 25% of cases of central pain in stroke are caused by lesions of the thalamus. Other lesion sites reported to be associated with central pain are the brainstem and parietal lobe projections from the thalamus. In the thalamic syndrome, patients report unremitting, unpleasant, burning pain affecting the opposite side of the body. Examination of the patient reveals contralateral impairment of all sensory modalities, often with dysesthesia. There may be involvement of adjacent structures, such as the internal capsule (hemiparesis, ataxia) or basal ganglia (choreoathetosis).

### Evaluation of the Stroke Etiology

For many patients, a stroke represents only one facet of systemic atherosclerotic vascular disease. Such patients will often have multiple risk factors for an event, such as increased age, hypertension, diabetes, and smoking. Stroke, however, can occur in the absence of common risk factors or atherosclerosis.

The investigation undertaken to identify the cause of a stroke depends on the patient's age and presence or absence of risk factors. For example, a 79-year-old man with hypertension and a long history of smoking who sustains a lacunar infarct will not likely require assessment for a hypercoagulable state, whereas this may be an important component of the investigation of the cause of stroke in a 32-year-old woman without identifiable risk factors.

A basic evaluation of stroke cause includes a thorough physical and neurological examination, cerebral imaging (CT or preferably MRI), an electrocardiogram, noninvasive carotid studies, and an echocardiogram. In cases where there is concern regarding a possible cardiogenic embolism, a 24-hour Holter monitor is appropriate. Transesophageal echocardiography provides superior imaging of left atrium, mitral valve, and the aortic arch. In cases where the possibility of a paradoxical embolism has been raised, the echocardiogram should include a “bubble” study to evaluate for right to left shunting, and studies for deep venous thrombosis are frequently performed. CT or MR angiography may be indicated when concerns regarding large vessel occlusion, stenosis, or dissection are present. Occasionally, conventional angiography may be indicated, although this is increasingly reserved for use during intravascular interventions.

In younger patients, evaluation frequently includes tests for a hypercoagulable state and screening for vasculitis or rheumatological disorder (e.g., lupus).

## STROKE IN CHILDREN AND YOUNG ADULTS

Stroke can occur at any age and is an important cause of disability in children and young adults. In a significant number of cases, 40% to 50%, no obvious risk factors—such as sources of cardiogenic emboli and atherosclerosis—are found. These

Drug induced

patients should be thoroughly investigated for primary etiology of the stroke. A list of possible diagnoses is given in Table 23-4. Coagulation disorders may be inherited or acquired, but they may account for up to 20% of cases with thrombotic infarction in young adults. Deficiencies of antithrombin III, protein C, and protein S are among the most important coagulopathies, as each of these substances is part of the naturally occurring anticoagulant system. Each of these coagulopathies requires long-term treatment with warfarin.

Carotid dissection may occur with minimal or no antecedent trauma and result in stroke in the MCA territory. Vertebral artery dissection may occur after high-velocity chiropractic manipulation of the cervical spine.

A variety of vasculitides may occur, some of which are part of multisystem autoimmune disease such as systemic lupus erythematosus. Another uncommon cause of stroke early in life is the inherited disorder homocystinuria, which predisposes individuals to early atherosclerosis. Lastly, stroke has been reported as an occasional complication occurring during pregnancy or in the postpartum period.

### Acute Stroke Management

The goals of acute stroke management are (a) to limit or reverse neurologic damage through thrombolysis or neuroprotection and (b) to monitor and prevent secondary stroke complications such as elevated intracranial pressure.

Intravenous thrombolysis with recombinant tissue plasminogen activator has been known to be effective when administered to appropriate individuals within 3 hours of symptom onset since the mid-1990s (31). While a recent study found

thrombolysis useful and acceptably safe as late as 4.5 hours poststroke in a selected population, it is clear that this intervention is most effective when given as early as possible (32). This has prompted major centers to develop stroke teams that can respond rapidly 24 hours a day with immediate clinical evaluation, urgent CT scan, and infusion as soon as possible within the therapeutic window. The ability of MRI to identify areas of mismatch between perfusion and diffusion has been studied as a means of identifying candidates for intravenous or intra-arterial thrombolysis outside of the standard time windows (33). Ultrasound has been used as a therapeutic tool in studies to enhance the thrombolytic effects of infused medications, although it is not yet been incorporated into routine clinical practice (34).

Thrombolytic agents are being administered intra-arterially in clinical trials and may prove an alternative to intravenous thrombolysis in patients who are not candidates for the latter procedure or as a salvage procedure in patients whose affected artery fails to recanalize with intravenous thrombolytic therapy (35). Clot removal devices, such as the Merci device, have been studied but are not yet in routine clinical use (36). A major challenge in the delivery of all of these therapies remains the delay in obtaining medical care among stroke victims (often due to a lack of recognition of the significance of their symptoms or by the severity of the deficits themselves), inability to identifying the time of onset, and the difficulty in providing these complex therapies in the required, time-dependent manner.

The development of an effective neuroprotective agent remains one of the major goals in acute stroke care but has thus far not been successful. Control of blood pressure, fever, and hyperglycemia have, however, been shown to improve outcome in acute stroke. Other approaches, such as brain cooling, remain under investigation.

Excitotoxicity is believed to play a role in the death of ischemic neurons in the penumbra around an infarction. Dying cells release excitatory amino acids, particularly glutamate, which activate cell membrane channels, allowing toxic levels of calcium to accumulate inside cells that are injured but not yet dead. The elevated intracellular calcium initiates an array of neurochemical changes within the neurons that generate free radicals and result in cell death. Clinical trials of glutamate receptor antagonists and free radical scavengers for acute stroke have been disappointing in humans, despite evidence of efficacy in animal models.

## Secondary Stroke Prevention

Secondary prevention involves a multipronged effort at risk factor reduction, which may involve behavioral change, such as smoking cessation, aerobic exercise, and dietary modifications in addition to optimizing treatment of associated medical risk factors, such as hypertension and diabetes.

The third aspect of secondary prevention is the use of specific medications for stroke prevention.

Antiplatelet medications are appropriate for the majority of patients for secondary prevention of ischemic stroke. Aspirin

in doses of 50 to 325 mg provides a reduction in stroke of approximately 25% (13). Gastrointestinal toxicity (bleeding, dyspepsia) is the most common side effect of aspirin, followed by allergies.

Clopidogrel is another antiplatelet agent with a different mechanism of action from aspirin. In clinical trials, its efficacy in preventing stroke is comparable to aspirin, though it is more costly. It is generally well tolerated, though its use has been associated with rare cases of thrombotic thrombocytopenic purpura. Combining clopidogrel and aspirin is generally not recommended, as the combination appears to raise the risk of hemorrhagic complications without further reduction in stroke risk (37). Ticlopidine is a related drug, with similar efficacy. It has largely fallen out of use due to concerns regarding neutropenia (24).

Another agent, dipyridamole, has some efficacy when taken alone but is generally prescribed as part of a fixed dose combination with aspirin (Aggrenox). In a large European trial, there was a 37% reduction in risk of stroke in patients prescribed both aspirin and dipyridamole (38), which compared favorably with treatment with aspirin alone. A recent study comparing dipyridamole with aspirin versus clopidogrel failed to show any difference in efficacy between these two therapies (39), and uncertainty regarding the ideal selection of antiplatelet agent persists (40).

Stroke can occur despite the use of antiplatelet agents. There is no consensus regarding the management of individuals who sustain a stroke despite preventive antiplatelet therapy, although substitution of combined aspirin plus dipyridamole therapy for aspirin monotherapy or substitution of clopidogrel for aspirin monotherapy is commonly instituted.

Warfarin use for stroke prevention is generally restricted to patients with atrial fibrillation or other known cardiac or other embolic source. For most indications, a target INR of 2 to 3 is used, although a higher range is needed for patients with certain types of mechanical heart valves.

Carotid endarterectomy reduces the risk of stroke in those patients with single or multiple TIAs and with 70% or greater stenosis of the ipsilateral internal carotid artery (41). Patients with stenosis of 50% to 70% may be considered for surgery if symptomatic, that is, if they are having TIAs or a stroke ipsilateral to the carotid lesion. The evidence for carotid endarterectomy is less compelling for patients with asymptomatic carotid stenosis, with a recommendation that it be considered for asymptomatic patients with stenoses of 60% to 99% (42).

Carotid stenting has been studied as an alternative to carotid endarterectomy, particularly in patients who may be at poor surgical risks. At present, there is no consensus regarding the relative efficacy, although some data suggest that endarterectomy provides better outcomes overall (43).

## Rehabilitation during the Acute Phase

The care of stroke survivors is organized in a variety of different systems around the world. In many European countries, stroke units provide a combination of acute stroke management and subsequent intensive rehabilitation in a single unit.

Studies of stroke units have consistently found improved outcomes when compared with care on general medical units (44). Interestingly, much of the benefits in mortality appear to relate to prevention and/or earlier recognition of medical complications of stroke and earlier mobilization (45).

In the United States, acute stroke care is often transitioned rapidly to rehabilitative care, often within a matter of days. Despite this, it is important that rehabilitation not be considered a separate phase of care, that only begins after acute medical intervention. Rather, it is an integral part of medical management and continues longitudinally through acute care, postacute care, and community reintegration. Although diagnosis and medical treatment are the principal focus of early treatment, rehabilitation measures should be offered concurrently. Many of these can be considered preventive in nature. For example, patients who are hemiplegic, lethargic, and incontinent are at high risk for developing pressure ulcers. Deliberate strategies should be followed to prevent skin breakdowns, including protection of skin from excessive moisture, the use of heel-protecting splints, maintenance of proper position with frequent turning, and daily inspection and routine skin cleansing (46).

Many patients with acute stroke have dysphagia and are at risk for aspiration and pneumonia. In the able-bodied, aspiration usually results in vigorous coughing, but as many as 40% of patients with acute stroke experience silent aspiration. Protection against aspiration (and resulting pneumonia) includes avoiding oral feeding in patients who are not alert. Even in alert patients, the ability to swallow should be assessed carefully before oral intake of fluids or food is begun. This is done with a bedside screening assessment that can be efficiently completed by physician or nursing staff and generally includes taking a small drink of water and observing for coughing or change in vocal quality (47). If any doubt exists about aspiration, a swallowing videofluoroscopy examination or flexible endoscopic evaluation of swallowing (FEES) is performed. During the acute phase, nasogastric tube feeding or gastrostomy tube placement may prove necessary. Patients who are lying flat in bed are at significant risk for regurgitation and aspiration, and the head of the bed should be kept elevated (48).

Impairment of bladder control is frequent following a stroke, which may initially cause a hypotonic bladder with overflow incontinence. If an indwelling catheter is used, it should be removed as soon as possible, with careful monitoring to insure that appropriate voiding resumes. For the occasional patient with persistent urinary retention after stroke, regular intermittent catheterization is preferable to an indwelling catheter (49).

Patients with hemiplegia are at high risk for development of contractures due to immobility. Spasticity, if present at this early stage, may contribute to the development of contractures through sustained posturing of the limbs. The harmful effects of immobility can be ameliorated by regular passive stretching and moving the joints through a full range of motion, preferably at least twice daily.

The risk of deep venous thrombosis is high, especially in patients with hemiplegia. Every patient should, therefore, have some form of deep vein thrombosis (DVT) prophylaxis, either subcutaneous heparin or external pneumatic compression boots or both.

Early mobilization is beneficial by reducing the risks of DVT, deconditioning, gastroesophageal regurgitation and aspiration pneumonia, contracture formation, skin breakdown, and orthostatic intolerance. Positive psychological benefits are also likely. Mobilization involves a set of physical activities that may be started passively but that quickly progress to active participation by the patient. Specific tasks include turning from side to side in bed and changing position, sitting up in bed, transferring to a wheelchair, standing, and walking. Mobilization also includes self-care activities such as self-feeding, grooming, and dressing. The timing and progression in these activities depend on the patient's condition. These activities should begin as soon as possible (generally within 24 to 48 hours of admission (49)) unless the stroke survivor is unresponsive or medically/neurologically unstable.

### Evaluation for Rehabilitation Program

Evaluation of longer-term rehabilitation needs should occur within the first few days after stroke. Many stroke survivors will benefit from admission to an acute rehabilitation hospital or unit (also known as an Inpatient Rehabilitation Facility), and criteria for admission into such a program are listed in Table 23-5. Some individuals may be more appropriate for a subacute rehabilitation program (based in a Skilled Nursing Facility), which provides a less intense rehabilitation program with a lesser degree of medical supervision over a longer period of time. These programs are most appropriate for individuals who are unlikely to return home due to premorbid conditions (such as dementia), who are too frail to undergo an intensive rehabilitation program, or whose neurological impairments are so profound as to prevent participation in a hospital-level program. Some individuals complete a period of intensive "acute" rehabilitation, followed by "subacute" rehabilitation, before returning home. Stroke survivors with isolated disabilities such as a partial aphasia, visual loss, or monoparesis may more appropriately receive rehabilitation on an outpatient basis or through a homecare agency.

**TABLE 23.5** Criteria for Admission to a Comprehensive Rehabilitation Program

Stable neurologic status
Significant persisting neurologic deficit
Identified disability affecting at least two of the following: mobility, self-care activities, communication, bowel or bladder control, or swallowing
Sufficient cognitive function to learn
Sufficient communicative ability to engage with the therapists
Physical ability to tolerate the active program (at least 3 h/d)
Achievable therapeutic goals

## RECOVERY FROM STROKE

### Compensation, Recovery, and Rehabilitation

Historically, rehabilitation focused primarily on instruction in compensatory techniques, such as ambulating with a cane and AFO, or the use of one-handed dressing techniques. With the increasing recognition of the plasticity of the adult human brain and the ability of rehabilitation interventions to facilitate this recovery, there has been a growing component of therapy intended to maximize recovery of neurological function. These approaches are at some level complementary, inasmuch as the goal of rehabilitation should be to maximize neurologic recovery and then teach compensatory approaches to address whatever residual deficits exist. Unfortunately, treatments for improvement of recovery during the early phases of stroke often require intensive efforts, and their benefits, while appearing hopeful, are still difficult to assess. As a result, limitations in the duration and intensity of rehabilitation supported by third-party payers have resulted in a continued clinical emphasis toward compensatory approaches, even as the evidence demonstrating the opportunities to achieve partial neurological recovery continues to grow. Resolution of this tension remains problematic in the current health care environment.

### Recovery from Impairments

Hemiparesis and motor recovery have been the most studied of all stroke impairments. As many as 88% of patients with an acute stroke have hemiparesis (50). In a classic report, Twitchell (51) described in detail the “classic” pattern of motor recovery following stroke. In the majority of hemiparetic patients, the arm is more involved than the leg, and the degree of functional motor recovery in the arm is less than in the leg. There are several reasons for this preponderance. Perhaps the most important reason is that ischemic strokes, as noted above, occur in certain vascular territories more frequently than others. More specifically, strokes affecting the middle cerebral artery territory are much more common than those affecting only the anterior cerebral artery territory. The higher flow through the MCA and the more direct path for embolism may underlie this predilection for the MCA. In patients who do experience ACA territory infarcts, the usual pattern of arm impairment exceeding leg impairment is reversed, with the best preservation of motor function in the distal upper limb.

Another factor contributing to the discrepant outcomes between the upper limb and the lower limb is the very distinct functional demands placed on the upper versus the lower limb. The lower limb can be reasonably functional if it is able to maintain an extended posture and have some gross volitional movements. By contrast, the upper limb relies on the exquisite fine motor control of the hand for functional tasks, and gross movements (as are often recovered in the proximal portion of the upper limb) do not result in a substantial level of function.

The severity of arm weakness at onset and the timing of the return of movement in the hand are both important predictors of eventual motor recovery in the arm (52–55). The prognosis for return of useful hand function is poor when

there is complete arm paralysis at onset or no measurable grasp strength by 4 weeks. However, even among those patients with severe arm weakness at onset, as many as 11% may gain good recovery of hand function. Some other generalizations can be made. For patients showing some motor recovery in the hand by 4 weeks, as many as 70% will make a full or good recovery. Complete functional recovery, when it occurs, is usually complete within 3 months of onset. Bard and Hirschberg claim that “if no initial motion is noticed during the first 3 weeks, or if motion in one segment is not followed within a week by the appearance of motion in a second segment, the prognosis for recovery of full motion is poor” (53).

The patterns of motor recovery have been described in detail by the authors of the Copenhagen Stroke Study (56). Summary data are shown in Figure 23-1. Ninety-five percent of stroke survivors reached their best neurologic level within 11 weeks of onset. Individuals with milder stroke recovered more quickly, and those with severe strokes reached their best neurologic level in 15 weeks on average. The course of motor recovery reaches a plateau after an early phase of progressive improvement, and only minor additional measurable improvement occurs after 6 months postonset (57). However, in some stroke survivors who have significant partial return of voluntary movement, recovery may continue over a longer period of time. However, recovery varies from person to person, and it is important that these data are not misinterpreted as dictating a fixed course. The observation that stroke survivors with apparently chronic stable motor deficits can experience improved motor function as the result of an intensive exercise program even years after a stroke also creates a conundrum for clinicians seeking to determine a reasonable therapeutic end point for motor rehabilitation efforts.

Aphasia occurs in about one third of patients with acute stroke, although a substantial portion of affected individuals

**FIGURE 23-1.** The time course of recovery in stroke survivors shown as the cumulated rate of patients having reached their best neurological outcome. The course of recovery is given for patients whose initial stroke severity was mild, ◆; moderate, ▲; severe, \*; very severe, ●. All patients are represented by ■.

will improve. By 6 months or more after stroke, only 12% to 18% of stroke survivors have identifiable aphasia (58,59). The time course of recovery of language function is slower and more prolonged than motor abilities, with improvements continuing for more than a year in some cases (59). The course of recovery varies depending on the nature of the language impairments. Patients with Broca's (nonfluent) aphasia with large hemisphere lesions tend to have little recovery, whereas patients with smaller lesions (e.g., confined to the posterior frontal lobe) often show evolution into a milder form of aphasia with anomia and word-finding difficulty. Individuals with global aphasia (affecting both comprehension and verbal expression) tend to progress slowly, with comprehension often improving more than expressive ability. Communicative ability of stroke survivors who initially have global aphasia improves over a longer period of time, up to 1 year or more poststroke. Patients with global aphasia associated with large lesions may show only minor recovery, but those with smaller lesions may improve substantially. Language recovery in Wernicke's (fluent) aphasia is variable.

About 20% of patients have a visual field defect. In general, the degree of visual improvement following stroke is modest, and if the field defect persists beyond a few weeks, late recovery is less likely.

### Mechanisms of Neurologic Recovery

Neurological improvement begins immediately after the stroke and is believed to result from a number of mechanisms. Improvements seen in the first days to weeks after stroke appear to include recovery of function in portions of the ischemic penumbra and resolution of edema and associated mass effect. Overlapping with this early resolution and continuing for at least several months is the process of cerebral plasticity and functional reorganization of the cerebral cortex. Both animal and human studies with fMRI and other techniques have demonstrated alterations in cortical maps associated with this plasticity. Similarities exist between the processes of motor learning and motor recovery, and some overlap between these processes is likely. Some or all of the improvements in motor function observed with intensive training in stroke survivors with apparently stable deficits may be a result of motor learning, rather than "motor recovery" *per se* (60).

Plasticity is strongly influenced by use, as shown in both animal and human studies (61). Research is ongoing to determine the optimal training program to achieve maximal motor recovery. (See Chapter 81 for more details about neuroplasticity.)

### Specific Stroke Impairments and Their Rehabilitation

The initial examination of a patient with an acute stroke includes a thorough neurologic examination. The neurologic findings are used by the rehabilitation team for prognostication, development of the rehabilitation plan, and selection of the appropriate setting for rehabilitation. Reassessment of the patient during rehabilitation provides a means of monitoring progress and subsequently evaluating outcome.

### Cognition and Communication

The impact of stroke on cognition and communication depends on several factors, including the size and location of the lesion and the presence or absence of premorbid factors such as prior stroke(s), dementia, or other neurologic conditions. Particularly among older stroke survivors, there is a high prevalence of premorbid cognitive decline, often undiagnosed prior to the stroke.

Delirium is also common during the early phases of acute hospitalization and may result from infection, sleep disruption, fluid or electrolyte disturbances, or medication side effects. Elderly patients are at increased risk of delirium, although stroke patients can be affected at any age. This delirium is generally reversible and should be recognized so that the underlying cause can be treated, so that efforts to prognosticate are not based on faulty impressions of the magnitude of the deficits directly related to the stroke.

Stroke can also affect a person's ability to maintain an alert and attentive state. Large hemispheric strokes may cause drowsiness, as can some lesions affecting the brainstem. Stimulants are frequently employed as treatment (such as dextroamphetamine or methylphenidate), as well as modafinil, often with partial benefit. Most patients with reduced arousal after a stroke tend to improve substantially over a period of days to weeks.

A bedside mental status assessment is an essential part of the assessment of every stroke patient. The Mini-Mental State Examination (MMSE) developed by Folstein et al. (62) is a useful bedside tool that screens a variety of mental demands quickly and gives a well-validated measure of overall mental function. It requires less than 10 minutes to administer. The NIH Stroke Scale (NIHSS) is another widely used measure that includes some elements of cognitive and language abilities. Neither the MMSE nor the NIHSS constitutes a full cognitive and linguistic assessment, and clinicians should tailor their examination to further explore and delineate the impairments identified on a basic assessment. Formal neuropsychological testing may be useful to develop a comprehensive assessment of cognitive and linguistic functions but is usually best deferred until stroke survivors have completed a portion of their rehabilitation and are approaching a stable plateau in ability.

Perceptual impairments, in which the primary sensory system is intact but the processing of the sensory information is impaired, are common among stroke survivors, particularly (but not exclusively) those with nondominant hemisphere lesions. Left hemispatial neglect may be accompanied by a right gaze preference in severe cases, but more subtle impairments may require formal testing to identify. Commonly used bedside tests for visual neglect include letter cancellation tasks or line bisection.

Hemispatial neglect may affect some forms of stimuli more than others, such as visual, tactile, or auditory. Therapies commonly include the use of visual and/or verbal cuing, including having the patient learn to cue himself or herself verbally to look to the left side. Fresnel prisms applied to eyeglasses are

sometimes used to shift images in the affected hemivisual field toward the center of the retina and hence into the field of view, although benefits are unclear, patient acceptance is limited, and use is not widespread (63).

Strokes affecting the right parietal lobe also commonly cause deficits in constructional ability, and patients may be unable to copy or draw simple figures (or omit elements on the left side). Other bedside tests of perceptual function are failure to recognize palm writing (graphesthesia), inability to identify objects in the hand (astereognosis), and extinction of simultaneous bilateral stimulation.

Anosognosia, a lack of ability to recognize the deficits resulting from the stroke, is common among individuals with right parietal lesions and may include a lack of awareness of hemiplegia, a lack of insight regarding their need for continued hospitalization, and, in severe cases, an inability to recognize their hemiplegic limb(s) as their own.

The term *apraxia* describes the inability of an individual to execute an intended movement when motor and sensory functions are apparently preserved. Apraxia is a disorder of motor planning, rather than of coordination (such as ataxia) or of motor strength and control (such as hemiparesis). Ideomotor apraxia may be detected when a person is unable to carry out a task on command such as “comb your hair” or “wave good-bye,” even though there is no paralysis. This type of apraxia is most common in individuals with dominant hemisphere strokes. Patients with lesions of the nondominant parietal lobe may have apraxia of dressing.

A variety of behavioral changes can occur after stroke and reflect the anatomy of the brain damage. Individuals with frontal lobe damage may display reduced attention and abulia. In more severe frontal lesions (generally bilateral), severe abulia may result in akinetic mutism. Apathy is common, manifesting as a lack of concern regarding one’s personal condition and reduced insight and concern regarding the impact on friends or family.

Deficits in attention and executive function are very common following a stroke and can occur in association with frontal, parietal, or temporal lesions. Stroke survivors may show reduced ability to maintain attention to a task, inability to switch from one task to the next, or inability to filter out unimportant stimuli in the environment with resulting distractibility. Deficits in attention are commonly misinterpreted as memory impairments, as individuals who are not attending to stimuli and information provided will be unable to recall it at a later time.

Dementia, particularly in its milder forms, may have been present before a stroke and is often unrecognized and undiagnosed by clinicians during the early recovery period. Stroke itself may cause multi-infarct dementia, and patients with multiple lesions, especially when bilateral, are more likely to show features of dementia. Numerous studies have shown that in patients with a history of stroke, those with more extensive white matter changes are at higher risk for dementia.

Poststroke depression is very common and is discussed in greater detail below. Emotional lability occurs in as many as 20% of patients poststroke and is more common in patients with right hemisphere lesions. Individuals with emotional lability often are unable to control or suppress their emotional response to common environmental stimuli and may cry or laugh very easily even though the stroke survivor recognizes that this response is inappropriate. Emotional lability (sometimes termed “emotional incontinence”) is often mistaken for depression. Education of the stroke survivor and his or her family is particularly important, and many individuals find they can tolerate these symptoms reasonably well as long as they understand their cause. Emotional lability tends to improve with time and may respond partially to treatment with tricyclic or selective serotonin reuptake inhibitors (SSRI) antidepressants (64–66).

## Communication Disorders

Communication is a complex function involving reception, central processing, and expression of information (see Chapter 15). Communication occurs through the use of language and consists of a system of symbols that are combined to convey ideas, that is, letters, words, or gestures. Impairment of language is called *aphasia*, and its presence reflects an abnormality in the dominant hemisphere. *Speech*, on the other hand, is a term that refers to the motor mechanism involved in the production of spoken words, namely breathing, phonation, and articulation. Dysphonia and dysarthria are disorders of speech. The inflection and intonation of speech (prosody) are also important in communicating and may be impaired after right hemisphere stroke (aprosodia).

There are a number of aphasia classifications. In the simplest classification, aphasia is divided into two main categories: motor aphasia (sometimes called nonfluent, expressive, or anterior aphasia), characterized by nonfluent speech, and sensory aphasia (sometimes called fluent, receptive, posterior, or Wernicke’s aphasia), characterized by fluent speech (see Table 23-6) (67). Anomic aphasia is a milder form of aphasia, where difficulty recalling the correct words or names is most prominent. Simple bedside tests can allow the clinician to categorize the communication disorder. Questions typically addressed during the bedside assessment of aphasia are provided in Table 23-7. Comprehensive evaluations of patients can be performed using formal aphasia tests. Table 23-8 summarizes the more commonly used formal aphasia test instruments.

Language therapy is based on the detailed evaluation of the patient’s cognitive and linguistic capabilities and deficits. In the early stages of rehabilitation, it is important for the therapist to help the patient establish a reliable means for basic yes/no communication. The therapist then progresses to specific techniques based on the patient’s deficits. Specific techniques have been described for improving comprehension, word or phoneme retrieval, and gestures to supplement verbal communication. Recovery of functional communication may have a

**TABLE 23.6** Classification of Aphasia

Classification	Fluency	Comprehension	Repetition	Naming
Global	Poor	Poor	Poor	Poor
Broca	Poor	Good	Variable	Poor
Isolation	Poor	Poor	Good	Poor
Transcortical motor	Poor	Good	Good	Poor
Wernicke	Good	Poor	Poor	Poor
Transcortical sensory	Good	Poor	Good	Poor
Conduction	Good	Good	Poor	Poor
Anomic	Good	Good	Good	Poor

more protracted course than motor recovery, and meaningful improvements may be seen in some stroke survivors 6 and 12 months after stroke and beyond. A meta-analysis found speech therapy effective for aphasia (68), although a Cochrane review (69) has found insufficient evidence to draw this conclusion. More recently, a dose-response effect has been identified, with more intensive therapy correlated with greater improvement (70). Newer methods of therapy, including Constraint-Induced Aphasia Therapy (involving intensive practice of speech tasks with which the stroke survivor has difficulty) are being explored (71).

### Visual Deficits

Visual field deficits are common among patients with strokes in the middle cerebral artery or posterior cerebral artery distributions. Bedside testing of visual fields, including examination for extinction with simultaneous stimulation, is an important element of the clinical evaluation of stroke patients undergoing rehabilitation. More formal visual field testing may prove useful in selected patients but is seldom necessary. Patients with isolated visual field deficits, but without concomitant hemispatial neglect, generally learn to compensate effectively. A number of therapist-directed and computer-based

training (e.g., Vision Restoration Therapy, Novavision, Inc.) approaches have been developed to facilitate improving the size of the functioning visual field, although their overall benefits remain debated.

Strokes in the brainstem can cause extraocular palsies and associated diplopia. Patching is often useful to prevent diplopia; patches may be alternated between eyes when appropriate to allow practice of extraocular movements and facilitate recovery of the paretic muscles.

### Dysphagia

Dysphagia may affect 40% of patients with a unilateral hemispheric stroke (72) and is an important risk factor for pneumonitis and aspiration pneumonia. It generally has a favorable prognosis (48,73) but may be more severe and persistent in patients with brainstem lesions or with bilateral hemispheric strokes (74).

Dysphagia may affect either or both the oral preparatory pharyngeal phases of swallowing. Bedside evaluation of a patient includes observation of the function of the lips, tongue, cheeks, and jaw and elevation of the larynx during swallowing, as well as vocal quality. Having the patient swallow a small amount of water (30–90 mL) at the bedside provides considerable information about oral control, the timeliness of swallowing, presence or absence of a wet vocal quality, and the presence or absence of coughing. Patients who are drowsy should be considered unsafe for oral intake by virtue of their altered level of consciousness, and further assessment deferred until they are more awake.

If an initial screening examination suggests dysphagia, a more extensive bedside evaluation by a speech and language pathologist (or, in some facilities, an occupational therapist) is generally advisable. Some patients aspirate “silently” (without coughing), and the overall results of the bedside assessment should guide decisions regarding more extensive assessment (75). A videofluoroscopic swallowing study (VFSS) (also called a modified barium swallow) provides detailed information about the swallowing mechanism and allows for

**TABLE 23.7** Bedside Aphasia Assessment

Questions	Clinical Test
Does the patient understand?	Give verbal commands, ask the patient to point to objects.
Is the patient able to talk?	Ask the patient to name objects, describe them, and count. Listen for spontaneous speech.
Can the patient repeat?	Ask the patient to repeat words.
Can the patient read?	Give commands in writing.
Can the patient write?	Ask the patient to copy or to write dictated words.

**TABLE 23.8** Commonly Used Formal Aphasia Tests

- The Boston Diagnostic Aphasia Examination (32) produces a classification of the aphasic features observed in a particular patient. Besides classifying the aphasia, it also provides a score of the severity of the aphasia, which can be compared to aphasic patients in general (38).
- The Western Aphasia Battery (39) is somewhat similar to the Boston. It measures various parameters of spontaneous speech and examines comprehension, fluency, object naming, and repetition. It provides a total score called an aphasia quotient, which is a measure of the severity of the aphasia.
- The Porch Index of Communication Ability (PICA) is different from the other tests in that it evaluates verbal, gestural, and graphic responses. It is very structured in its format and must be given by a trained professional. It provides a useful statistical summary of the details of the language impairments and offers outcome prediction.
- The Functional Communication Profile (40) provides an overall rating of functional communication. It is not a diagnostic test. The score indicates severity and can be a useful indicator of recovery.

direct visualization of aspiration. Moreover, modified food consistencies, such as thickened liquids, and compensatory swallowing maneuvers, such as a chin tuck, may be tested during the course of the fluoroscopic swallowing study to determine if they result in safer swallowing.

FEES is another technique that allows more direct visualization of the swallowing process and is used in some settings as an alternative to VFSS, particularly when VFSS is unavailable (e.g., at a nursing home) or logistically impractical (a patient who cannot be moved to the radiology suite for a VFSS for medical reasons). While it does not allow direct visualization of aspiration, FEES does provide considerable information that complements the bedside examination and avoids the radiation exposure present with VFSS.

Both compensatory and recovery strategies are useful for dysphagia. Modified food consistencies, such as pureed foods or thickened liquids, are widely used, as are physical maneuvers, such as a controlling food bolus size and pacing, or using a “chin tuck” or double swallow. It appears likely that practicing swallowing over time improves performance and may enhance the process of spontaneous recovery.

For patients who cannot swallow safely, a nasogastric, gastrostomy, or jejunostomy tube is indicated for enteral feedings. None of these tubes are entirely effective in preventing aspiration pneumonia, in part because oral secretions may be the source of aspiration pneumonia, rather than feedings. Nasogastric and gastrostomy tubes both permit aspiration through the mechanism of gastroesophageal reflux as well, especially when patients are placed flat in bed. The selection of a feeding tube depends on several factors, including patient preference, anticipated duration of the use of a feeding tube, and procedure-related risks. Nasogastric tubes often prove problematic for longer term feeding due to frequent dislodgement, tube blockages, and patient discomfort, and therefore, gastrostomy tubes are often favored if the duration of the feeding tube use is expected to be lengthy. While most individuals with hemispheric stroke recover good swallowing function, those with brainstem lesions or bilateral hemisphere lesions may progress more slowly, and some require indefinite use of a feeding tube. Some individuals recover the ability to ingest sufficient food before they are able to drink

enough liquids to maintain adequate hydration—in these cases, a feeding tube may continue to be required for fluid supplementation.

A surprising number of patients admitted for stroke rehabilitation are malnourished—as high as 22% in one report (76). Elderly patients may have marginal nutritional status prior to their stroke, and if not closely monitored during post-acute rehabilitation, their fluid and nutritional status may be further compromised because of dysphagia, reliance on others for oral or tube feedings, lack of interest in food, depression, and problems with communication. The risk of malnutrition and dehydration is very real in even the most alert appearing patient and intake of fluid, protein, total calories, and body weight should be monitored closely in all patients. Oral nutritional supplements may have to be prescribed, and if a patient continues to have inadequate intake, enteral tube feeding may be necessary.

### Motor Impairment

Strength, power (the speed with which force can be generated), motor control and coordination, muscle tone, and balance may all be affected by stroke. The most widely used clinical scale to assess strength is the Medical Research Council’s (MRC) 6-point scale, 0 to 5, in which 0 represents complete paralysis, 3 is the ability to fully move the limb against gravity, and 5 indicates normal strength (77). This scale is useful in grading muscle strength in patients with lower motor neuron lesions or myopathies but is problematic for assessing stroke survivors. Stroke survivors will often be able to activate a muscle group to varying degrees depending on the position of the limb and coactivation of synergistic muscles. Thus, a stroke survivor may be able to generate considerable force when grasping in association with wrist and elbow flexion but have much less ability to selectively flex the fingers in isolation. Also, the failure of this scale to indicate the degree of motor control may lead to misinterpretation, as in the example of a patient who can generate considerable force, but who has limited motor control, and whose MRC score is recorded as normal or near normal. Despite these shortcomings, the MRC scale is widely used by clinicians, often supplemented by qualifying descriptions (e.g., “elbow flexion is 4/5 on MRC scale in a flexion

**TABLE 23.9** Brunnstrom Stages of Motor Recovery

Stage	Characteristics
Stage 1	No activation of the limb.
Stage 2	Spasticity appears, and weak basic flexor and extensor synergies are present.
Stage 3	Spasticity is prominent; the patient voluntarily moves the limb, but muscle activation is all within the synergy patterns.
Stage 4	The patient begins to activate muscles selectively outside the flexor and extensor synergies.
Stage 5	Spasticity decreases; most muscle activation is selective and independent from the limb synergies.
Stage 6	Isolated movements are performed in a smooth, phasic, well-coordinated manner.

From randstater ME. Basic aspects of impairment evaluation in stroke patients. Adapted from: Chino N, Melvin JL, eds. *Functional Evaluation of Stroke Patients*. New York: Springer-Verlag; 1996:9–18.

synergy pattern with moderately reduced motor control”). Use of a dynamometer (78) to measure force generation requires more time and similarly fails to assess motor control and thus has a limited role in the measurement of paresis in stroke survivors.

Brunnstrom (79) adopted a different approach for assessment of motor function in hemiplegic patients in which movement patterns are evaluated and motor function is rated according to stages of motor recovery (Table 23-9) (67). While this rating can be performed very quickly, the scale defines recovery only in broad categories. Moreover, not all hemiparetic stroke survivors progress through these “stages” sequentially, with some survivors skipping stages during their recovery. For these reasons, this scale has not achieved widespread clinical or research usage.

Despite the limitations of assessing and interpreting muscle strength in patients with upper motor neuron lesions, strength does correlate with performance on functional tasks (80). Fugl-Meyer et al. designed a more detailed and comprehensive motor scale in which 50 different movements and abilities were rated (81). The test evaluates strength, reflexes, and coordination, and a composite score is derived on a scale of 0 to 100. The Fugl-Meyer Scale is reliable, and repeat scores reflect motor recovery over time. It is widely used in the research setting but has not been widely adopted by clinicians because it is time-consuming to complete. A variety of other motor scales have been developed to provide a more comprehensive picture of motor function (rather than merely impairment), which are primarily utilized in a research setting, such as the Wolf Motor Function Test (82), Motor Activity Log (83), the Arm Research Action Test (84), and others.

*Spasticity or Muscle tone* refers to the resistance felt when the examiner passively stretches a muscle by moving a limb and generally increases if the stretching is performed more quickly (velocity dependent). Abnormal increases in muscle tone are quite commonly seen in hemiparetic limbs, and patients with more severe spasticity tend to have less well-preserved motor control. Factors such as posture and limb position can affect spasticity and must be considered when measuring muscle tone. Scales for measuring spasticity remain of limited reliability, with the most widely used being the Ashworth Scale

(see Chapter 50, Spasticity) (85). Most spasticity can be managed conservatively with stretching and positioning. In cases where medical therapy is needed, treatment with oral antispasticity medications, such as baclofen or tizanidine, is often ineffective and may cause sedation or cognitive impairments. The use of injection therapy (principally botulinum toxin, but previously more commonly phenol or alcohol injection) is generally effective in reducing spasticity, although it does not ameliorate the underlying impairments in motor control.

## Therapy for Motor Weakness

### Early Phase and Supportive Care

In the early poststroke phase, the hemiparetic limb(s) may be completely paralyzed and are at high risk for the development of contractures or nerve pressure palsies. Therapy during this early phase should consist of proper positioning of the patient in bed and support of the arm in a wheelchair trough when sitting. Traction on the arm should be avoided when the patient is moved or transferred to a wheelchair. All joints of the affected limbs should be passively moved through a full range of motion at least once daily to prevent contractures.

If the limb(s) become quite spastic, frequent slow stretching can help to reduce tone. Spasticity usually dominates in the flexors of the upper limb and may hold the wrist and fingers in a constant position of excessive flexion. A static wrist-hand orthosis is often helpful in maintaining these joints in a functional position.

## MOTOR RECOVERY

Motor recovery may become evident within hours to days after a stroke. A variety of approaches have been advocated to facilitate and enhance motor recovery, including traditional approaches, such as the neurodevelopmental technique advocated by Bobath (86), functionally oriented exercise training (such as practicing transfers and early ambulation), and a recent focus on repetitive task-oriented practice. Neurodevelopmental (NDT) exercises are intended to normalize muscle tone and prevent excessive spasticity using special reflex-inhibiting postures.

Other traditional techniques, such as the system developed by Rood, involve superficial cutaneous stimulation using stroking, brushing, tapping, and icing or muscle stimulation with vibration, to evoke voluntary muscle activation. Brunnstrom emphasized the synergistic patterns of movement that develop during recovery from hemiplegia. She encouraged the development of flexor and extensor synergies during early recovery, hoping that synergistic activation of muscle would, with training, transition into voluntary activation. Proprioceptive neuromuscular facilitation (PNF) was developed by Kabat and colleagues and relies on quick stretching and manual resistance of muscle activation of the limbs in functional directions, which often are spiral and diagonal. Generally, there is little empiric evidence supporting the use of these techniques (NDT, Brunnstrom, Rood, PNF) which are increasingly being replaced with functional task-oriented approaches.

Newer techniques, such as Constraint-Induced Movement Training (CIMT) (87) and robot-aided exercise (88), have been increasingly incorporated into clinical protocols. CIMT utilizes an intensive short course (generally 2 weeks) of upper limb training with repetitive task-oriented practice and behavioral shaping techniques to enhance not only motor control of the upper limb but also incorporation into behavioral repertoires. The mechanism underlying this improved function remains uncertain. Taub (who developed this technique) initially hypothesized that this therapy was able to overcome a “learned nonuse” of the weak limb, in which the potential for improved motor function is present but not incorporated into actual usage (89–91). The identification of changes in cortical mapping using transcranial magnetic stimulation (61) and in activation of the primary and supplementary motor cortex using fMRI (92) suggests that cortical reorganization of the motor systems is an important underlying mechanism for the effects of this treatment. Other task-oriented practice techniques have also shown efficacy (93), and research on identifying the optimal exercise regimen is ongoing. Logistic and cost considerations have limited the availability of Constraint-Induced Movement Therapy, as has the suitability of this therapy for only a modest range of deficits. Modifications of Constraint-Induced Movement Therapy are being studied in an effort to provide a more logistically feasible treatment program (94).

Robot-aided therapeutic exercise has several potential advantages over conventional therapies as it provides consistently delivered therapy and is particularly suitable for highly-repetitive exercises. Most robotic systems provide assistance to users attempting movements and thus can be used by individuals with more severe paresis after stroke. Upper limb devices, such as the InMotion2 (Interactive Motion Technologies, Cambridge, MA), have been shown to provide benefit in both the acute (95,96) and chronic phases of stroke (88). Lower limb robotic systems have been developed for gait training, as discussed below (“Therapy for Mobility”). While these devices hold the promise of providing more efficient therapy, the current generation requires skilled assistance (from a therapist or

aide) in setting the patient up and in supervision of treatment. Robotic therapy has not been proven superior to comparably dosed hands-on therapy. Robotic therapy is discussed in greater detail in Chapter 83.

Electrical stimulation of the limb (sometimes termed therapeutic electrical stimulation or functional neuromuscular stimulation) has long been used in some form since the 1960s as a treatment for hemiparesis, with some recent evidence accumulating that it may be beneficial in restoring motor use to some extent (97). Please see Chapter 71 for a more extensive discussion of this therapy.

Biofeedback using electromyogram (EMG) signals has been used in an attempt to improve motor control poststroke. Results of trials have been mixed, some showing benefit but others no better results than control therapy. While one review of clinical trials of biofeedback did find that biofeedback was somewhat effective (98), the magnitude of the benefits is small, and clinical use in the United States is relatively rare. Conventional EMG biofeedback involves recording surface EMG from the test muscle and using auditory or visual display of the EMG signal as feedback to the patient on the activity status of the muscle. The EMG signal supplements conventional reeducation given by the therapist. A combination therapy in which therapeutic electrical stimulation is triggered by the EMG signal of the target muscle is available (99). In another approach, robotic devices that relay on surface EMG signals to control or trigger the device are being studied (100).

## THERAPY FOR MOBILITY

In the early phase after stroke, some individuals will not have sufficient trunk control and hemiparetic leg strength to maintain upright posture for walking. These patients should receive initial therapy to develop gross trunk control and training in pre-gait activities such as posture, balance, and weight transfer to the hemiparetic leg. As recovery progresses, stroke survivors usually develop better gross motor skills and trunk balance and greater strength in the leg. Despite the presence of spasticity and the inability to selectively activate individual muscles, most stroke survivors will walk, although many will require an ankle-foot orthosis and cane and will walk more slowly than previously. Individuals with less severe paresis may have an asymmetric gait but not require a brace for their affected leg. Many stroke survivors will require a cane for walking, which may be a standard cane or, less commonly, four pronged, depending on their balance impairments. While hemiparesis often makes it impossible to use a walker effectively, individuals with milder paresis or other stroke-related balance impairments such as ataxia may find a walker helpful.

There have been reports that hemiplegic patients benefit from intensive gait training when therapy consists of walking on a treadmill with body weight partially supported (PBWSTT) with a harness (101,102). The harness substitutes for poor trunk control, and the motor-driven treadmill forces locomotion. During early training, the patient is assisted by

two or three therapists in controlling the trunk, pelvis, and weak leg. Treadmill training with body weight support appears superior to conventional therapy with improved gait velocity resulting (103). Progressive increase in treadmill speed as tolerated accentuates this benefit (103).

Robotic therapy has been proposed as an alternative to PWBSTT training, in part because of the need for two or even three staff members to assist the patient during a treatment session. Robotic devices, such as the Lokomat (Hocoma, Inc.) and the ReoAmbulator (Motorika, Inc.), are now commercially available for this purpose. While the feasibility of this approach has been demonstrated (104), there is evidence that therapist-assisted locomotor training with a treadmill is more effective (105). Continued enhancement of the robotic devices and treatment algorithms may result in increased efficacy of robotic therapy in the future.

### Sensory Impairment and Central Pain

Sensory impairment may occur with or without accompanying motor weakness following a stroke, although loss of proprioception generally results in reduced motor performance even in the absence of weakness *per se*. Lesions of the thalamus may cause severe contralesional sensory loss and result in a central pain syndrome in some individuals. Central pain can occur, particularly with strokes involving the spino-thalamo-cortical pathway. The pain usually begins a few weeks after stroke onset and becomes intractable to conventional medications, including opiate analgesics. The pain is classically described as burning in character, although other types of pain can predominate.

With lesions of the cortex, primary sensory modalities may be preserved, but the perception of these sensations may be both qualitatively altered and quantitatively reduced. Perceptual impairment, as often seen in parietal lobe lesions, frequently is manifested as inability to perceive stimulation of the affected side during simultaneous bilateral stimulation (extinction), reduced two-point discrimination, reduced object recognition (stereognosis), and impaired recognition of digits drawn in the palm (graphesthesia).

Regrettably, few interventions have been proposed to specifically treat sensory loss after stroke, although a variety of pharmacological treatments have been studied for treatment of central pain poststroke. Tricyclic antidepressants have been best studied for this condition, although some patients do not have an adequate response, and anticholinergic side effects can be problematic (especially in the elderly). Anticonvulsants, such as gabapentin or lamotrigine, show some efficacy as well (106,107).

## OUTCOME AND PROGNOSTICATION IN STROKE REHABILITATION

Patients, their families, and members of the health care team all benefit from an accurate prognosis to help inform decision

making. The prospects for survival, the degree of recovery that may be expected, and the extent of possible residual disability following rehabilitation are all important elements of prognosis.

The challenge in developing accurate prognostic models is not surprising, given the myriad of complex functions performed by the brain, the variability of stroke lesion location and size, the limitations of our assessment techniques, and the impact of many baseline factors on stroke recovery, such as age, comorbid conditions, personality and coping abilities, and social factors.

### Predicting Survival

Early death following a stroke is usually related to the underlying pathology, the patient's age, and to the severity of the lesion. For patients with a first cerebral infarction aged 45 to 64, survival is 88% to 92% at 30 days; for those aged 65, the survival rate is similar. By contrast, for patients with hemorrhagic stroke (including SAH), the survival is reported to be only 62% to 63% for those aged 45 to 64, falling to 55% for those aged 65 and older (1). Coma following a stroke onset indicates a poor prognosis, presumably because coma occurs frequently in cerebral hemorrhage, and when it occurs in relation to cerebral infarction, it reflects a large lesion with cerebral edema.

### Predicting Disability and Functional Status

The key outcomes from a rehabilitation perspective are restoration of function and community reintegration. The central purpose of the rehabilitation program is to lessen ultimate disability; therefore, considerable attention has been directed at the identification of factors that will predict the functional outcome of the patient, especially with respect to walking and activities of daily living (ADLs).

The prognosis for recovery from lacunar lesions is usually excellent, although significant persisting deficits may occur when the lesion is strategically located. With large vessel infarctions, due either to thrombosis or embolism, prognosis is related to the volume of the lesion. Outcome is poorest when the lesion involves more than 10% of intracranial volume (108).

While many stroke survivors are initially unable to walk independently, 54% to 80% achieve this milestone within the first 3 months poststroke (although frequently requiring the assistance of a cane or AFO) (59,109). Data from the Framingham cohort reported by Gresham et al. (110) indicate that long-term survivors of stroke show good recovery of functional mobility, with 80% being independent in mobility.

Most patients with significant neurologic impairment who survive a stroke are initially dependent in basic ADLs, that is, bathing, dressing, feeding, toileting, grooming, transfers, and ambulation. The capacity of individuals to perform these activities is usually scored on ADL scales, such as the Functional Independent Measure (FIM<sup>R</sup>) (111). Almost all patients show improved function in ADLs as recovery occurs. In most reports, between 47% and 76% of survivors achieve

partial or total independence in ADLs (112–114). Basic ADL scales, such as the FIM, while sensitive to changes during the early phase of rehabilitation, have limited sensitivity at the upper end of the functional range and ceiling effects. Instrumental ADLs, such as the ability to prepare meals or perform housework, are not measured by the FIM yet represent an important component of reintegration into the community for stroke survivors.

Most authors who have attempted to determine which factors predict ultimate ADL functional outcome have used multivariate analysis. The single most useful predictor of functional outcome is the initial ADL assessment (most commonly, the FIM score). Other important variables include age and sitting balance. A list of important variables predicting outcome is given in Table 23-10. Not all of these factors were shown in every study to statistically predict outcome status.

The effect of age on outcome may partly be related to more frequent comorbid diseases and functional impairments, rather than merely a result of age *per se*.

Intuitively, it would seem reasonable to assume that patients with more severe neurologic deficits would have worse functional outcomes, but this is not necessarily the case when isolated neurologic impairments are considered. For example, analyses of predictive variables have failed to show that patients with sensory deficits have a poorer ultimate outcome than those with preserved sensation (115). When considering functional independence as the outcome measure of interest, the severity of the initial ADL score is generally one of the more reliable predictors of ultimate ADL function. On average, patients admitted for rehabilitation with lower ADL scores do not have as good a functional outcome as patients who initially had higher admission ADL scores. Most patients with FIM scores of greater than 80 are discharged home, although many other factors influence discharge disposition (116).

It is important that rehabilitation begins as early as possible. The Post-Stroke Rehabilitation Outcomes Project demonstrated that patients have better outcomes if they are admitted into a rehabilitation program early rather than later, regardless

of severity of the stroke (117). In addition to enhancing recovery, early rehabilitation and mobilization appear to reduce the likelihood of secondary complications, such as contractures and deconditioning, and help patient motivation.

### Social Variables

Stroke survivors with severe disabilities who need maximum physical assistance in ADLs and who have bowel or bladder incontinence are the most likely to require long-term institutional care (112). While functional status is the most important issue in determining discharge destination, psychosocial factors, especially prestroke family interaction (118) and the presence of an able spouse, also influence whether the patient returns home. A supportive family whose members are willing and able to provide significant physical care may be able to manage a severely disabled patient at home. By contrast, a patient with much less disability but no family support may require institutional care if not fully independent.

When a clinician is confronted with the challenge of evaluating an individual patient, guidelines for predicting functional outcome are useful but are not precise because multiple variables interact. A patient who might be judged as having a good prognosis for functional outcome may do poorly because of a negative psychosocial factor. The best estimate of prognosis can be made only after a thorough and comprehensive evaluation of the patient's medical, neurologic, functional, and psychosocial statuses.

## MEDICAL MANAGEMENT DURING REHABILITATION

There is a high incidence of comorbid medical disorders among patients recovering from stroke, reflecting the age of the patient population and the fact that cerebrovascular disease is often part of a generalized disease process. If severe, or if poorly managed, these disorders may interfere with the patient's participation in the rehabilitation program and may adversely affect outcome. Similarly, medical complications frequently occur during the postacute phase of rehabilitation, affecting as many as 60% of patients and as many as 94% of patients with severe lesions (119). Common medical and neurologic complications are listed in Table 23-11 (110,112–114). Some of the important and more frequent disorders are discussed briefly.

### Cardiac Disease

In a large majority of patients, a stroke is an acute event in the course of a systemic disease, for example, atherosclerosis, hypertensive vascular disease, or cardiac disease causing embolic stroke. As many as 75% of stroke patients may show evidence of coexisting cardiovascular disease, including hypertension (estimates range from 50% to 84%) (120) and coronary artery disease (as many as 65%) (120). Another group of heart diseases cause a stroke through cardiogenic cerebral

embolism. These diseases include atrial fibrillation and other arrhythmias from multiple causes, valvular disease, cardiomyopathy, endocarditis, or recent myocardial infarction.

Concomitant heart disease has a negative impact on short-term and long-term survival and probably on functional outcome of stroke patients (121,122). Acute exacerbations of heart disease occur frequently during postacute stroke rehabilitation (121). Common problems include angina, uncontrolled hypertension, hypotension, myocardial infarction, congestive heart failure, atrial fibrillation, and ventricular arrhythmias. Development of one of these complications may have minimal or no impact on the patient's progress or outcome if the problem is promptly diagnosed and appropriately treated. However, these complications often do impact the patient's capacity to participate fully in the therapeutic program. Congestive heart failure and angina decrease exercise tolerance and reduce capacity to roll over in bed, transfer, and walk.

### Urinary Tract

Urinary function can be affected in several ways by stroke, including urinary infection, urinary retention, and urge incontinence. At the time of the acute stroke, some patients develop urinary retention due to altered mental status or direct effects of the stroke on the neurological control of micturition. Premorbid voiding dysfunction, often in the form of benign prostatic hypertrophy in men and stress incontinence

in women, is a common comorbid condition in stroke patients and often becomes a more significant problem after a stroke due to the patient's decreased mobility or communication abilities. Catheterization, often with an indwelling catheter, is common during the acute management of the stroke survivor. While this alleviates acute urinary retention, it may lead to urinary infection and interferes with reestablishment of a normal voiding pattern. Indwelling catheters should be removed as quickly as possible, and intermittent catheterization substituted for individuals unable to void spontaneously. Noninvasive measurement of bladder volume using ultrasound is often helpful when managing individuals with impaired bladder function after stroke.

While urinary retention generally resolves quickly in affected stroke survivors, many stroke survivors develop urinary urgency and/or incontinence. Disinhibition of the bladder detrusor is common and results in urinary frequency and urgency that may result in incontinence in some individuals. Anticholinergic medications such as oxybutynin chloride (Ditropan) or tolterodine (Detrol) are useful to inhibit bladder contraction, although these may cause anticholinergic side effects, such as dry mouth, or confusion.

## MUSCULOSKELETAL PAIN AND COMPLEX REGIONAL PAIN SYNDROME

Shoulder and arm pain is common following a stroke in survivors. It tends to develop early, several weeks to 6 months postonset, and some studies have found as many as 72% of individuals affected, especially those with more severe hemiplegia (123). More recent studies suggest a lower incidence, with one study finding 37% of patients on a stroke rehabilitation unit reporting pain (124). This apparent reduction in incidence may reflect more intensive and earlier rehabilitation programs incorporating range-of-motion exercises.

Although some patients may have preexisting shoulder problems, such as rotator cuff tendinitis, the pain in most patients with hemiplegia results from varying combinations of glenohumeral subluxation, spasticity, and contracture. Of these, subluxation is the commonly implicated cause. The role of subluxation in generating shoulder pain has been debated, and subluxation may occur without pain symptoms in many individuals. Subluxation is evident on physical examination, and imaging studies are not generally useful unless other diagnoses are being considered. Treatment of a subluxed shoulder in poststroke patients can limit the subsequent development of shoulder pain (125). Some cases of shoulder pain appear related to spasticity of shoulder girdle muscles (e.g., the subscapularis), although it is unclear how often this is the actual cause of pain versus an unrelated finding.

Preventative measures to reduce the likelihood of developing shoulder pain should be instituted early poststroke in patients with flaccid paralysis of the upper limb and clinically evident subluxation or with any symptoms of shoulder pain. Proper positioning includes supporting the arm in an

arm trough or lapboard when seated and avoiding traction on the arm when transferring. Selective use of supportive slings during ambulation or standing is advisable, although their use negatively impacts balance. Excessive use may contribute to undesirable reduction in opportunities to use the upper limb and potentially slow functional recovery and cause loss of range of motion. In cases where spasticity appears responsible for pain, the use of botulinum toxin or phenol injections may be appropriate (126).

The incidence of upper limb complex regional pain syndrome (CRPS, also known as reflex sympathetic dystrophy or shoulder-hand syndrome) remains controversial. Some studies have reported a high prevalence of 1 in 8 based on clinical criteria and up to 1 in 4 using bone scan criteria (127,128), but these figures appear inflated by inclusion of other causes of upper limb pain in hemiplegic stroke survivors, including patients with pain related to shoulder subluxation and some with central pain syndromes. Preventative measures, including frequent passive range of motion, desensitization with massage, and active incorporation of the paretic upper limb in the therapy program, are important and may have contributed to the apparent reduction in the frequency of this syndrome. Please see Chapter 49 for a discussion of treatments such as oral steroids in established cases of CRPS.

## VENOUS THROMBOEMBOLISM

All patients with significant immobility related to stroke should receive DVT prophylaxis, which should consist of either low-dose subcutaneous heparin or low molecular weight heparin, with the latter somewhat more effective in high-risk individuals. Treatment with low-dose low molecular weight heparin reduced the risk of DVT (odds ratio 0.34) without an increase in the risk of major intracranial or extracranial hemorrhage (129). In patients who cannot safely receive these medications, external pneumatic compression devices are an effective alternative, particularly in the acute hospital phase. Although many rehabilitation units attempt to use pneumatic compression in addition to or instead of pharmacological treatment, their use in this setting is problematic due to the patients' involvement in out of bed activities. The optimal duration of prophylaxis remains uncertain, although most practitioners discontinue its use once patients are walking significant distances on a frequent basis or at the time of discharge to the community.

All patients with suspected DVT should undergo prompt investigation by venous duplex ultrasound imaging. Routine screening examinations are not generally used in this population at present. Symptoms may be subtle or absent, and therefore, physical examination is not reliable enough to confirm or exclude this diagnosis (130).

Patients with newly diagnosed DVT should immediately receive full-dose anticoagulation with low molecular weight heparin (or occasionally intravenous conventional heparin) until a therapeutic INR (between 2 and 3) can be achieved with the use of warfarin for at least 2 days. Patients with acute

DVT are commonly placed on bed rest for 24 hours, although the value and optimal duration of this practice remain debated, and some guidelines recommend immediate ambulation when feasible (131). In patients who cannot safely receive anticoagulation (most commonly those with a recent intracranial hemorrhage), an inferior vena cava filter should be inserted to prevent pulmonary embolism.

## DEPRESSION

Depression is common following stroke and, depending on diagnostic criteria, has been reported in as many as 50% of patients (132,133). Some have reported a relationship between left frontal or bifrontal lesions and major depression (134), though this may be an artifact of the language function needed to complete the commonly used depression assessment scales that interferes with accurate measurement of depression in aphasic patients. Multiple theories exist for the high incidence of depression poststroke, which appears more common than would be expected merely as a result of the psychosocial stresses accompanying acquired disability. One hypothesis is that stroke may result in brain catecholamine depletion through lesion-induced damage to the frontal noradrenergic, dopaminergic, and serotonergic projections (135).

The diagnosis of poststroke depression may be complicated by the presence of normal sadness associated with the loss of independence, emotional lability that may result from stroke, and the high prevalence of symptoms often associated with depression (e.g., sleep disturbance, fatigue, altered appetite) that are known to result from stroke itself. Persistently depressed mood, loss of interest in socialization, and limited participation in the rehabilitation program are often more reliable indicators in this population (136).

Persisting depression correlates with delayed recovery and poorer ultimate outcome. Active treatment should be considered for all patients with significant clinical depression. Patients with poststroke depression generally respond well to standard antidepressant medications, with SSRIs commonly prescribed. Some practitioners will also treat with a stimulant medication (typically methylphenidate) in an attempt to "boost" the response and achieve more rapid results. A recent study found preventative treatment with an SSRI effective in reducing the frequency of poststroke depression, and some physicians are adopting this treatment approach for high-risk patients (137).

## SEXUALITY

Stroke survivors commonly experience sexual dysfunction (138), with reductions both in libido and sexual performance predominating, although occasionally stroke can cause hypersexuality. The precise mechanisms for sexual dysfunction after stroke have not been determined, but a combination of psychosocial and medical issues appears to be involved. Stroke is most common in people who are older, have hypertension,

and/or diabetics—all risk factors for sexual dysfunction even without a stroke. Moreover, sexual dysfunction is common in the adult population at large, with as many as 40% to 45% of adult women and 20% to 30% of adult men having at least one manifestation (139). Thus, some of the sexual dysfunction observed in this population may not directly result from the stroke.

Regardless of the specific cause(s), the prevalence of sexual problems after stroke is estimated to be between 57% and 75% (140,141). Sexual dysfunction is also very common among the sexual partners of stroke survivors and is likely due to a combination of psychosocial stressors and the reduced sexual availability of their usual partner due to the sequelae of stroke.

Many stroke survivors and their sexual partners harbor fears (sometimes not expressed) that resumption of sexual activity might precipitate another stroke. While limited data are available to directly address this concern, most practitioners agree that resuming sexual activity is safe and appropriate after discharge from the hospital in the vast majority of cases. This is largely based on extrapolation from studies that have found a low risk of myocardial infarction from resumption of sexual activity (142).

The natural history of sexual dysfunction after stroke appears favorable in most cases. In one study of men with stroke, 82% of those who experienced erectile dysfunction after stroke improved spontaneously within a few months. The degree of dependence in ADLs is a strong predictor of decreased sexual frequency among stroke survivors (143,144).

It is important to recognize that some sexual dysfunction after stroke may be iatrogenic and a result of medications used to treat stroke-related conditions. In particular, SSRI antidepressants, such as fluoxetine and paroxetine, are well-known to cause sexual dysfunction in as many as 30% to 70% of those receiving them without concomitant medical issues such as stroke. Similarly, antihypertensives, including  $\beta$ -blockers in particular, are a common cause of sexual dysfunction. Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers are generally better tolerated from this perspective. Lastly, anticonvulsant medications are well-established causes of reduced libido and sexual dysfunction (145).

Phosphodiesterase-5 inhibitors, such as sildenafil (Viagra) and tadalafil (Cialis), are useful for selected men with poststroke erectile dysfunction. Caution should be exercised with regard to potential medication interactions, including  $\alpha$ -blockers and nitrates.

Generally speaking, physicians and other health care professionals caring for stroke survivors should inform stroke survivors of their willingness and availability to discuss sexuality after stroke and provide further information to patients and their sexual partners when desired. Embarrassment on the part of both the patient and the physician is often a barrier to discussing this subject, as are implicit assumptions about sexuality (e.g., a physician assuming that an older widowed individual is not sexually active). Reassurances regarding the safety of resuming sexual activity are a particularly critical aspect of this counseling.

## Ongoing Care

The observations that continued improvement in motor function is possible in stroke survivors even after years of stable chronic deficits have created both opportunity and challenge for rehabilitation providers. We do not yet know what the ideal rehabilitation program consists of, particularly with regard to intensity and duration of therapy. Uncertainty regarding the maximal achievable outcomes for stroke survivors both preserves hope for our patients and creates complexity for practitioners.

Furthermore, stroke survivor's other rehabilitation needs may extend for many years after the initial event. Late issues may include depression, spasticity, contracture, osteoporosis, weight gain, and deconditioning due to reduced activity. The gradual progression of some of these issues, such as gradual loss of range of motion resulting from spasticity and inadequate stretching, may result in functional loss without the patient seeking medical care. Patients with substantial residual disability from a stroke likely benefit from periodic psychiatric assessment on an ongoing basis.

# Traumatic Brain Injury

## NATURE OF TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) is one of the major causes of disability worldwide. The systematic study of the residual effects of TBI can be traced to World War II and the work of Alexander Luria, Kurt Goldstein, and others (1,2). In this early work, much was learned about the deficits following penetrating injuries to the brain in soldiers with gunshot wounds. The pattern of residual dysfunction often corresponded to a focal lesion caused by the bullet passing through the brain. These focal deficits were similar to those observed in strokes.

Most TBIs are classified as closed head injuries, wherein the skull is not actually penetrated. The nature of injury sustained in vehicular accidents and falls (e.g., blunt impact, acceleration-deceleration) often results in multifocal lesions and diffuse brain damage with a variety of physical, cognitive, and neurobehavioral impairments that are unique to each person and pose formidable obstacles to community integration. Modern international conflicts involving the use of improvised explosive devices have led to a new injury mechanism—blast injury—the biophysics and clinical outcomes of which are not yet fully understood (3).

TBI affects all age groups. However, complex issues are posed by children with TBI because the injury interacts with the processes of biological, psychological, and social development. The special problems of children with TBI are not treated in detail here, but there are excellent sources for additional information on this topic (4,5). At the other end of the age spectrum, one finds the older adult with brain injury, whose recovery tends to be slower than the younger population and may be complicated by preexisting comorbidities and the reduced plasticity of the aged brain (see also Englander and Cifu, 1999 for a review of this topic (6)). Given the increasing percentage of older persons within the general population, it is likely that a growing number of survivors of brain injury will be in this subgroup.

## The Range of Outcomes: Death to Complete Recovery

Injury type and severity vary widely. In some injuries, commonly referred to as *concussions* or *mild traumatic brain injuries*, the person may suffer only a period of confusion or a brief episode of unconsciousness. Most of those with mild TBIs return to normal activity within days. In a minority of cases, somatic, cognitive, and affective symptoms may persist for weeks, months, or longer. Mild brain injuries constitute the

vast majority of TBIs. At the other extreme, death from severe brain injury is estimated at 20.7/100,000 population, which represents a 22% decline from 1979 (7). Most rehabilitation efforts are focused on survivors of moderate and severe TBI, among whom 80 to 90,000 survive each year with disability. Nearly 2% of the U.S. population requires ongoing assistance with activities of daily living (ADL) as a result of a TBI (8,9).

## Measures of Injury Severity

Both *depth* and *duration* of coma have been considered to be indices of the severity of TBI. Clinical assessment of coma was made more precise and objective with the advent of the Glasgow Coma Scale (GCS) in the 1970s (10), a quantitative measure of the depth of unconsciousness (Table 24-1). *Coma* is defined as not opening the eyes, not obeying commands, and not uttering understandable words. A GCS score of 8 or less in the acute period is operationally defined as a comatose state (11). Ironically, however, the use of the GCS as a marker of injury severity has become more problematic with changes in emergency management, in that increasing numbers of patients are intubated and subjected to chemical paralysis in the field, making it impossible to record an accurate GCS score. The Full Outline of Unresponsiveness (FOUR) is a recently developed measure of depth of unconsciousness that adds assessment of brainstem reflexes, and does not require verbal responding, thus avoiding the confound of intubation. The FOUR is of comparable reliability to the GCS (12), but it does not avoid the problem of chemical paralysis and is too new to have accumulated a large volume of prognostic data.

Duration of coma is often defined as the time until the patient resumes following commands. Both duration of coma and initial GCS score have been reported to predict neurobehavioral outcome from TBI (13,14), varying with the outcome measures selected and the time since injury. Stein and Spettell (15) showed that when the GCS was modified slightly to include complications such as intracranial lesions, its predictive power was improved.

The duration of *posttraumatic amnesia* (PTA) has been used as a measure of injury severity as long ago as the 1930s (16). During PTA, patients are out of coma but remain disoriented and amnesic for day-to-day events. Duration of PTA is measured from the onset of TBI to the resumption of ongoing memory; the duration of coma, if any, is thus included. Researchers have used PTA as an index of injury severity and an important predictor of outcome (17,18). Retrospective

**TABLE 24.1 Glasgow Coma Scale**

Examiner's Test	Patient's Response	Assigned Score
Eye opening		
Spontaneous	Opens eyes on own	4
Speech	Opens eyes when asked in a loud voice	3
Pain	Opens eyes when pinched	2
Pain	Does not open eyes	1
Best motor response		
Commands	Follows simple commands	6
Pain	Pulls examiner's hands away when pinched	5
Pain	Pulls a part of the body away when pinched	4
Pain	Flexes body inappropriately when pinched (decorticate posturing)	3
Pain	Body becomes rigid in an extended position when pinched (decerebrate posturing)	2
Pain	Has no motor response to pinch	1
Verbal response (talking)		
Speech	Carries on a conversation correctly and tells examiner where he or she is, month and year	5
Speech	Seems confused or disoriented	4
Speech	Talks so examiner can understand victim but makes no sense	3
Speech	Makes sounds that examiner cannot understand	2
Speech	Makes no noise	1

From Teasdale G, Jennett B. Assessment of coma and impaired consciousness. *Lancet*. 1974;2:81.

measurement of PTA duration from examination of medical records, or by asking the person to estimate the amnesic interval, can be unreliable. The Galveston Orientation and Amnesia Test (GOAT) provides an objective, widely used, and reliable way of measuring PTA prospectively (19). However, it has been criticized on the grounds that although it assesses orientation, it fails to capture the amnesia characteristic of PTA. An alternative, the Westmead PTA Scale, includes a measure of day-to-day memory as well as standard orientation questions (20). Duration of PTA, assessed prospectively with the Westmead, is a strong predictor of long-term outcome variables such as employment status (21–24).

The predictive power of PTA duration is better for patients whose brain damage is caused primarily by diffuse axonal injury (DAI) than for those with primarily contusions or other focal brain injury (25). Another alternative, known as the *Orientation Log* (O-Log), has been used increasingly and found to be easier to administer than the GOAT. Unlike the GOAT, the O-Log allows for cueing to assist individuals with language or severe memory impairments, and it does not require the patient to verify information about events relating to the injury (26). The initial O-Log score, combined with measures such as time since injury and number of O-Log administrations, accurately predicted resolution of disorientation in 76% of a sample of 389 individuals aged 10 to 93 years (27).

## EPIDEMIOLOGY OF TBI

The epidemiology of TBI varies with injury severity and mechanism. Based on 2003 estimates from the United States

Centers for Disease Control and Prevention (CDC), the overall incidence of TBI resulting at least in an emergency department visit was 538.2/100,000, meaning that approximately 1 in every 200 individuals sustains a TBI annually. The incidence of mild TBIs that do not lead to emergency department visits (i.e., are unevaluated or evaluated in a private physician's office) is unknown. The vast majority of individuals—nearly 80%—sustain a “mild” TBI (i.e., a concussion) and are discharged directly from the emergency department. The rate of hospitalization for mild TBI has declined substantially from 130/100,000 population in the 1970s to 51/100,000 in the 1990s, perhaps due to changes in admission criteria (8). Approximately 290,000 individuals are hospitalized and discharged alive annually (about 18.6% of the total), most of whom have moderate or severe injuries. More than 50,000 individuals (about 3.25% of the total or 15% of those with serious injuries), die prior to hospitalization or before hospital discharge (28) (Table 24-2).

The current rate of hospitalization represents an approximately 50% decrease from studies conducted 20 to 25 years ago. It is considered to be a reflection of substantially fewer “mild” cases being hospitalized, rather than a drop in incidence of TBI. Precise measures of prevalence within the population are unknown; however, the CDC estimates that approximately 5.3 million Americans are living with a TBI-related disability (29), with about 125,000 new individuals annually requiring assistance with ADL at least a year after their injuries (30).

These overall figures obscure significant differences in injury severity by age, gender, ethnicity, and mechanism of injury. For example, adults and men, on average, sustain more

**TABLE 24.2** Numbers and Rates of TBI-Related Emergency Department Visits, Hospitalizations, and Deaths by Age Group, United States 2003

<sup>a</sup>Numbers and rates may not sum to totals due to rounding.

<sup>b</sup>Rate per 100,000 population.

<sup>c</sup>Total includes 21 deaths with unknown age.

<sup>d</sup>Sample size is 30 to 59; the value of the estimate was reported but may not be stable.

Note: Emergency department visits does not include 247,000 hospitalizations, deaths, transfers, or persons with an unknown disposition. Hospitalizations do not include 21,000 persons who died in-hospital.

severe injuries than children and women (28). In addition, the rate of TBIs is elevated among African-Americans and Native Americans compared to other ethnic groups (30,31).

The most common etiologies of TBI include falls, motor vehicle accidents, and assaults, with falls now outnumbering motor vehicle injuries in many regions, as a result of the aging of the population. Motor vehicle accidents continue to have the highest fatality rates, however, and 40% to 50% of those injured were not wearing protective equipment (seat belts or helmets) at the time of injury (28). The mechanism of injury, however, also differs for different social groups, with injuries from firearms seen at the highest rate among middle-aged men (with rates on the decline), motor vehicle injuries seen most among adolescents and young adults (with rates also declining), and falls seen most among the elderly (with rates on the rise) (32). Elderly patients have higher death rates and a slower and less certain recovery process, compared with the young adult population (33).

A variety of risk factors have been identified as influential in determining who is likely to sustain a TBI. The most common factor cited is alcohol intake before the TBI (34). In the TBI Model System database as of 2001, approximately 50% of those screened for blood alcohol level (which includes about 80% of cases) were legally intoxicated at the time of injury (35). Other factors have been noted, such as preinjury personality disturbance, history of attention deficit hyperactivity disorder (ADHD) (36), family discord, or antisocial behavior, but little systematic research has been done to relate these factors to risk of injury (37). Helmet use by both motorcyclists and bicyclists reduces the severity of injuries that occur (38,39).

The economic and social impact of TBI is considered enormous but has not been extensively researched to date. In a study based on more than 300,000 individuals with TBI, Max

et al. estimated that the total lifetime cost for all people who sustained TBI in 1985 in the United States was \$37.8 billion (40). Charges for acute care and rehabilitation alone in the Model System database averaged about \$120,000 per patient, excluding physician charges (41). Estimates of return to work vary greatly, from 15% to 100%, depending on the admission criteria of the vocational program under study (42,43). In a population-based study, conducted without regard to whether or not individuals received vocational rehabilitation services, 47% of those with severe injuries who were working prior to injury, were working again 1 year later. Comparable figures for those with moderate and mild injuries were 78% and 81%, respectively (44). TBI creates strain in intimate relationships, affects role functioning, fosters economic hardship, and creates a great burden on the family (45). These issues are discussed further later in this chapter.

## PATHOPHYSIOLOGY OF TBI

### Primary Injury

Primary injury is defined as damage that occurs directly and immediately as a result of trauma to the brain. Cortical contusion and DAI are the two subtypes of primary injury. DAI is the distinguishing feature of TBI. Acceleration-deceleration and rotational forces that commonly result from motor vehicle accidents produce diffuse axonal disruption. The direction in which the force is applied affects the severity of injury, with lateral impact leading to poorer outcome than head-on or rear-end collisions (46). Depending on the severity of injury, such lesions may be microscopic, or they may coalesce into focal macroscopic lesions, with a preponderance in the midbrain and pons, corpus callosum, and white matter of the cerebral hemispheres

**FIGURE 24-1.** Brain regions particularly involved by diffuse axonal injury include the corpus callosum and parasagittal white matter as well as the dorsolateral quadrants of the midbrain. (From Auerbach SH. Neuroanatomical correlates of attention and memory disorders in traumatic brain injury: an application of behavioral subtypes. *J Head Trauma Rehabil.* 1986;1:1–12. Reprinted with permission of Aspen Publishers, Inc. © 1986.)

(47,48) (Fig. 24-1). DAI is also seen in areas where there is a change in the underlying tissue density, such as the gray-white interface, or where axons bend or change direction (49).

DAI is primarily responsible for the initial loss of consciousness (50). The precise mechanisms of axonal damage remain controversial but include direct axonal shearing and disruption of the intra-axonal cytoskeleton that may lead to axonal swelling and disconnection (51). Such injury may be a risk factor for development of Alzheimer's dementia (52). Animal data suggest that some of the loss of axonal integrity may happen after a delay (51), allowing the possibility that preventive treatments may be developed.

Cerebral contusion is the other main type of primary injury. These cortical bruises commonly occur at the crests of

the gyri and extend to variable depths, depending on severity. Contusions often occur on the undersurface of the frontal lobes, as well as the frontal and temporal tips, regardless of the site of impact, due to the internal architecture of the skull (Fig. 24-2). The lesions usually are bilateral but may be asymmetric. Coup-contrecoup injuries are more likely seen when the moving head hits a stationary object, such as with a fall. In this situation, one may see a contusion at the site of impact as well as another, often larger, contusion on the opposite cortex. Cerebral contusions may produce focal cognitive and sensory motor deficits and are risk factors for seizure disorders but are not directly responsible for loss of consciousness. In contrast to DAI, contusions may result from relatively low-velocity impact such as blows and falls. A given patient's pattern of functional

**FIGURE 24-2.** Areas predominantly affected by cortical contusions. *Shading* represents more frequently involved areas. Anterotemporal and orbitofrontal regions are particularly involved. Note relative sparing of dorsolateral frontal lobe and medial temporal lobe. (Adapted from Courville CB. *Mythology of the Central Nervous System*. Mountain View, CA: Pacific Press; 1937; with permission.)

deficits may be more focal (e.g., from contusions) or diffuse (e.g., from DAI) or may include features of both. The balance of these two pathologic features influences the nature of neurobehavioral deficits. Deficits related to DAI tend to recover gradually, with the pace of recovery inversely related to the duration of coma, whereas recovery from deficits related to cortical contusions depends more on the size and location of the focal injury (25).

### Secondary Injury and Initial Neurosurgical Management

Secondary injury can be defined as any damage to brain tissue that takes place after the initial (primary) injury. Whereas the only intervention for primary injury is prevention (with the possible exception of regenerative treatments), secondary injuries are at least to some degree treatable and theoretically preventable. The primary injury may set in motion a variety of pathologic processes that result in more severe and widespread brain damage. These processes range from subcellular events to those involving multiple organ systems and often work in concert. Apoptosis and excitotoxicity are examples of intracellular processes that lead to secondary injury, but can be driven by factors taking place at the tissue or systemic level. Local ischemia may lead to direct neuronal necrosis or initiate excitotoxicity by increasing levels of extracellular glutamate (53). This, in turn, leads to influx of calcium into neurons, which activates a number of proteases and increases the production of free oxygen radicals, resulting in intracellular injury and cell death (54). The local ischemia may be a result of several factors including direct trauma to blood vessels, systemic hypoxia, and cerebral hypoperfusion.

Cerebral hypoperfusion is assessed by evaluating the *cerebral perfusion pressure* (CPP), which is defined as the difference between mean arterial pressure (MAP) and intracranial pressure (ICP). Any factor that increases ICP or decreases MAP can decrease CPP, leading to increased ischemic injury. Management of CPP requires consideration of the pressure dynamics within the cranium, which is essentially a closed structure that contains brain tissue (cells and extracellular fluid), blood, and cerebrospinal fluid (CSF). Increases in the volume of any of these components will increase ICP. Expanding extra-axial or intraparenchymal hematomas, acute hydrocephalus, and brain edema are well-known causes of increased ICP, whereas systemic hypotension reduces CPP by decreasing MAP.

There is class II evidence to support a recommendation for maintaining CPP between 50 and 70 mm Hg (normal value for adults: 70 to 100), whereas data suggest that aggressive efforts to keep CPP above 70 mm Hg increase the risk of developing adult respiratory distress syndrome (55). Current guidelines recommend ICP monitoring in patients with severe head injury (GCS of 3 to 8) and an abnormal computed tomography (CT) scan (hematomas, contusions, edema, or compressed basal cisterns); or a normal CT scan and two out of three adverse features (age >40, unilateral or bilateral motor posturing, or systolic blood pressure <90 mm Hg) (56).

Increased ICP is not treated in isolation. However, current guidelines recommend initiation of intervention when ICP is greater than 20 mm Hg. A number of options exist to decrease ICP. Bolus doses of the osmotic diuretic mannitol may be employed for increased ICP secondary to edema, providing MAP is maintained through adequate fluid replacement (57). There is increasing interest in the role of hypertonic saline as hyperosmolar therapy as well (58). Use of high-dose sedatives such as propofol and pentobarbital is also supported (55). Hyperventilation, which had been a mainstay for the management of high ICP, is now only recommended in very specific cases, while corticosteroids are not recommended at all, and are in fact contraindicated for persons with moderate and severe TBI (55). A craniectomy is another strategy used to decrease ICP, by increasing cranial volume. A recent review did not identify randomized, controlled studies to support this intervention in TBI, although some less rigorously designed trials have suggested utility. Randomized trials are ongoing (59).

Systemic factors such as anemia, hypotension, pulmonary injury, and cardiac or respiratory arrest also may contribute to secondary injury by diminishing the delivery of oxygen to the injured brain. Brain infection may occur from open skull fractures, CSF rhinorrhea, or iatrogenically from ICP monitoring. Prolonged seizures also can lead to secondary injury through increased metabolic requirements, disruption of spontaneous respiration, direct injury, and aspiration.

### Neurodiagnostic Tools

Many imaging and neurophysiological technologies are available to assist in TBI management. In the acute postinjury period, CT scanning can detect intracranial hemorrhage, brain swelling, hydrocephalus, and infarction. The raw data can be adjusted to better evaluate structures of different radiodensities, for example, bone windows to identify skull fractures. However, CT is not sensitive in identifying small contusions, white matter injury, or in the evaluation of the posterior fossa (60). In the postacute phase, CT scanning can be useful, especially when a patient's neurological status is deteriorating or failing to progress as anticipated. In such situations, CT may identify progression of hydrocephalus or hygromas, evidence of increased ICP, or new bleeds.

MRI has some advantages over CT, including lack of x-ray exposure, greater resolution in the brainstem, better identification of isodense collections of blood, and detection of small white matter lesions (61). However, MRI takes longer to perform, and requires that the patient not have any MRI-incompatible implants or equipment. In the broadest sense, CT is of greatest use in the acute setting, while MRI may be more appropriate in the subacute and chronic setting.

It is important to note that the absence of findings on CT or MRI does not rule out a TBI (62). Newer neuroimaging techniques may be more sensitive to structural and functional changes in the brain after trauma. Diffusion-weighted MRI (DWI) has been utilized to identify cytotoxic edema and to quantify the size of lesions after TBI. Studies have been carried out to correlate this with outcome (63). DWI has also been

used to increase the sensitivity of MRI in detecting DAI (64). More recently, diffusion tensor imaging, a technique derived from DWI, has also been utilized to determine the presence of DAI as well as evaluate changes in white matter tracts over time (65,66).

It may be that functional imaging can play a role in evaluating the brain after TBI due to its ability to provide information about the metabolic activity of specific regions at rest as well as during mental activities. Single photon emission CT (SPECT), positron emission tomography (PET), and functional MRI (fMRI) can all measure regional cerebral perfusion, although only PET and perfusion fMRI can quantify blood flow in absolute terms. Since perfusion may be compromised in structurally intact brain tissue, either as a result of reduced vascular delivery, or reduced perfusion demand by inactive neural tissue, reductions in flow may identify areas of functional compromise (67). Some fMRI studies conducted later postinjury have found that individuals with TBI demonstrate more widespread cortical activation during mental tasks than uninjured controls, suggesting that increased mental effort is required to perform tasks after injury. This finding has been seen in mild TBI as well as with more severely injured persons (68,69).

Another technique that is based on MRI technology is magnetic resonance spectroscopy (MRS). Although MRS studies utilize conventional MRI systems, they require different software that detects and quantifies certain brain metabolites that may be markers of particular pathophysiologic processes. For instance, choline can be measured, and levels may be related to the degree of membrane injury from DAI and other pathological processes (70). Glutamate may be a marker for metabolic abnormalities associated with brain injury (71). Shutter et al. have reported that MRS data obtained early in the acute hospital stay can be highly predictive of 6- and 12-month Glasgow Outcome Scale (GOS) scores, especially when combined with clinical data such as GCS motor subscore (72).

### **Neuroprotection, Neuronal Recovery, and Functional Recovery**

Recovery from TBI often is incomplete. Reports have identified subtle but persistent deficits after even mild TBI (73,74). Yet, many people who sustain TBI make tremendous gains from coma to the reemergence of a variety of complex skills. This recovery is believed to occur at multiple levels, from alterations in biochemical processes to changes in family structure (75). A better understanding of the pathophysiological mechanisms involved in secondary injury, as well as an improved understanding of the processes that underlie functional recovery may lead to improved treatments to restore function in injured individuals.

As mentioned previously, there is an increased understanding regarding the mechanisms that contribute to secondary injury. Thus, in theory, interventions could be designed that block various ion channels, scavenge free radicals, inhibit excitatory neurotransmitters, or block the internal signals for programmed cell death, thereby salvaging a greater proportion

of neural tissue that is not irreversibly damaged by primary injury. Despite the theoretical promise, however, the clinical trials that have studied such interventions have been generally disappointing (76). There are many possible reasons for the failure to identify useful neuroprotective treatments, including the heterogeneity of pathophysiologic mechanisms at work, difficulties in extrapolating from animal models, outcome measures chosen, and the possible need to combine different therapeutic mechanisms to maximize impact (77,78). An active search for additional neuroprotective agents continues, with some preliminary promising results (79–82).

Once a given degree of brain damage has occurred, a number of processes, overlapping in time and pathobiology, contribute to functional recovery. Restoration of effective perfusion and oxygenation, resolution of edema, and weaning of sedating drugs can lead to improvements in function in the first days and weeks after injury. Latent neuronal circuitry may be unmasked by injury, supporting functions that were previously carried out by neurons that are no longer functioning (83). Experience, often in the form of intense practice, has been shown to alter sensory-motor cortical representations (“maps”) in healthy humans as well as lesioned animals, suggesting that appropriately structured therapy might directly contribute to improved function after brain damage (84–86). Other interventions such as transcranial magnetic stimulation may also positively influence plasticity and cortical reorganization after TBI but await rigorous assessment (84). Resolution of diaschisis, either spontaneously, or through the actions of neurotransmitter agonists, may also play a role, and receptor antagonists may slow down recovery (85–87). Animal studies of neural transplantation are in progress and human trials in more focal neurological conditions have already appeared (88). At a more behavioral level, a person with a particular deficit may discover (or be taught) another strategy to accomplish the task that relies on remaining intact neural systems (89). Finally, as long as an individual is conscious and retains some learning capacity, it may be possible for them to learn specific tasks and activities, even though their overall capacity may remain fixed.

Although there is considerable evidence for several recovery mechanisms, particularly in the animal literature, there is as yet limited systematic application of these principles to the design of human rehabilitation efforts. Nevertheless, the growth of basic science research related to neural recovery is increasingly being translated into clinical research, with the anticipation of more theoretically based rehabilitation efforts in the future (90).

## **OUTCOME AFTER TBI**

### **Types of Deficits**

The majority of survivors of severe TBI emerge from coma and achieve remarkable progress toward regaining their preinjury functional abilities. Most, however, are left with a combination of physical and neurobehavioral impairments, which

collectively result in activity limitations and reduced societal participation. Each individual's specific pattern of deficits is a consequence of the severity of the injury, nature of brain damage, and medical complications, varying greatly from one person to the next. However, deficits in cognition, particularly affecting attention, memory and/or executive function, as well as fatigue are nearly ubiquitous after moderate or severe TBI.

Changes in behavior, mood, and personality after TBI may be the most difficult impairments to manage effectively. Behavior problems range from minor irritability or passivity to labile emotional displays or disinhibited, bizarre, or aggressive behavior. The severely brain-injured person may appear ego-centric and childlike, and may display a loss of empathy and concern for others.

Limitations in activities related to self-care, toileting, mobility, basic communication, and feeding commonly occur in severe TBI. In those with less severe injuries, difficulties may not be revealed until more complex community-oriented skills are attempted, such as time and money management, community mobility, and school or vocational tasks. Restrictions in vocational, educational, and interpersonal domains are widespread. There is frequently loss or diminution of friendships and intimate relationships, growing psychological distress, and a devastating impact on the family system. The psychosocial consequences of TBI, and the cognitive and behavioral impairments that underlie them, are reviewed in greater detail later in this chapter.

### Outcome Measurement

The measurement and prediction of outcomes have taken on increased importance in health care generally and rehabilitation specifically. There are several distinct uses for outcome measurement, with different implications for the types of outcomes measured and their interpretation. Outcome data for clinical program evaluation systems in brain injury rehabilitation are required by the Commission for the Accreditation of Rehabilitation Facilities (CARF), with the intent of ensuring that the types of functional outcomes achieved by each program are reasonable with respect to programmatic goals. However, the quality of functional outcomes achieved by clinical programs is a function of demographic and clinical characteristics of their client populations as well as the effectiveness of their treatment services. Consequently, comparison of the quality of different programs can only be made after appropriate "case mix adjustment"—a technique that is still in a rather primitive state.

Outcome measurement can also identify treatments that appear promising in producing outcomes superior to the prior standard of care, which can then be confirmed in controlled research. Highly accurate outcome prediction could also, in principle, guide individual treatment decisions. For example, if it could be predicted in the first few days postinjury that a patient would remain permanently vegetative, the physician and the family might choose not to pursue aggressive treatment; if independent ambulation were predicted not to be possible, the energies of physical therapy could be redirected

to other goals, and a definitive wheelchair could be prescribed earlier. For outcome prediction to be used in this way, however, it would need to be highly accurate in projecting the specific outcomes of individual patients; unfortunately, this goal has not been achieved.

The outcome scale used in many studies of acute TBI is the GOS. It has been demonstrated to have a high degree of interrater reliability (91). It has been used to correlate early injury severity measures (e.g., GCS, length of PTA) and outcome at 6 months postinjury. Several major drawbacks in the utility of the scale for rehabilitation purposes have been identified:

- The categories are so broad that it is not a sensitive measure of progress during rehabilitation.
- The global categories do not provide a real indication of functional abilities.
- Cognitive and behavioral dysfunctions are poorly addressed in the outcome categories.

Despite these limitations, it continues to have widespread use for its intended purpose—to provide a quantitative, general way of describing outcome. An extension of the GOS, the GOS-extended (GOS-E) seeks to remedy some of the shortcomings of the GOS by providing a broader range of outcome scores to improve sensitivity (92), and by incorporating a comparison with preinjury status in both medical and psychosocial domains (93) (Table 24-3).

Several other outcome measurement scales have been developed to be more sensitive to functional changes that are of interest in rehabilitation. Some of these are brain-injury-specific, and others are general rehabilitation scales.

**TABLE 24.3 Glasgow Outcome Scale-Extended**

1	Dead
2	Vegetative state (VS) No cerebral cortical function that can be judged by behavior (not able to follow simple commands or communicate)
3	Lower severe disability (lower SD) Needs full assistance in ADL throughout the day
4	Upper severe disability (upper SD) Needs some supervision/assistance in ADL, but can be alone for >8 h/d
5	Lower moderate disability (lower MD) Independent in ADL, and can shop and travel independently on public transportation, but has not returned to previous position or lifestyle
6	Upper moderate disability (upper MD) Able to resume previous position or lifestyle with alternative/modified duties or part-time due to injury
7	Lower good recovery (lower GR) Able to resume previous position or lifestyle (may be modified), but reporting some problems
8	Upper good recovery (upper GR) Complete return to previous lifestyle with no reported problems

The Disability Rating Scale (DRS) was developed specifically for TBI and is intended to assess changes “from coma to community” (94). This scale produces a quantitative index of disability across ten levels of severity, with high interrater reliability, and is considerably more sensitive to clinical change than is the GOS, particularly at the severe end of the spectrum, with less sensitivity to improvement within higher levels of functioning (95,96).

The Rancho Los Amigos Levels of Cognitive Functioning Scale focuses on cognitive recovery after TBI and the capacity to interact effectively with the environment. Each level is accompanied by a lengthy description of behaviors that meet the criteria for placement at that level (97). A comparison of this scale with the DRS revealed that it has slightly lower validity and reliability (98).

The Functional Independence Measure (FIM), an 18-item rating scale, is the most widely used outcome measurement scale in medical rehabilitation, and is now incorporated into the federal prospective payment system for inpatient rehabilitation. Although the FIM contains both motor and cognitive subscales, its scoring is weighted toward the physical items, and it fails to strongly capture the individual’s capacity for self-direction. Because of the relative insensitivity of the FIM to cognitive and behavioral deficits, the Functional Assessment Measure (FAM) was developed to supplement it with more cognitively oriented items. Interrater agreement for the FAM is lower (67%) than for the FIM (88%), and although it extends the range of difficulty somewhat compared to the FIM alone, its items are highly redundant with existing FIM items in terms of their scoring (96).

All the outcome scales discussed until now are well suited to measuring the changes that occur during acute rehabilitation, but they focus primarily on the activity level of the World Health Organization’s International Classification of Functioning, Disability, and Health (ICF) (99) and none of them adequately addresses higher-level functions for those with mild injuries or for those with severe injuries who have been discharged into the community (100).

Measures of behavioral and social functioning in the community that have been developed specifically for TBI outcome measurement include the Neurobehavioral Functioning Inventory (NFI) (101) and the Mayo-Portland Adaptability Inventory (MPAI) (102). The NFI is a self-report measure of the frequency of neurobehavioral symptoms, completed by either the injured person or a family member, that yields subscale scores in six domains of emotional/behavioral function: depression, somatic, memory/attention, communication, aggression, and motor. Both construct validity and criterion-related validity were demonstrated to be acceptable (103). However, this measure lacks sensitivity to the more subtle long-term problems in the domains of executive function and social behavior (104). The MPAI was developed to provide an evaluation of progress during postacute brain injury rehabilitation. It is a 30-item rating scale completed by staff or survivor on two fundamental dimensions derived from a principal components analysis: Physical/Cognitive Impairment Scale

and Social Participation Scale. Both person reliability (0.82) and item reliability (0.96) were found to be good to excellent (102).

The first outcome measure developed specifically to measure community functioning of persons with brain injury was the Community Integration Questionnaire (CIQ) (105). This 15-item questionnaire has been demonstrated to consist of three subscales: home integration, social integration, and productivity. It can be completed by the person with brain injury or a significant other. The CIQ has been found useful as a measure of “objective” quality of life and level of productivity, but has also been subject to criticism for its psychometric properties (106). Another measure of community functioning, originally developed for persons with spinal cord injury, is the Craig Handicap Assessment and Reporting Technique (CHART) (107). This measure focuses on measurement of handicap or participation restriction. Original subscales included physical independence, mobility, occupation, social integration, and economic self-sufficiency. A revised version of the scale, which included a dimension identified as Cognitive Independence, was developed more recently (108). This additional scale also showed high test-retest reliability (0.87) in a mixed sample of individuals with neurologic illness including TBI and was also found to be a useful tool in evaluating postacute functioning in persons with TBI (109).

Neither the CHART nor the CIQ measures change relative to preinjury. One measure that does so and has both patient-rated and relative versions is the Sydney Psychosocial Reintegration Scale (SPRS) (Form A) (110,111). It comprises 12 items covering three domains: occupational activity (OA); interpersonal relationships (IR); and independent living skills (LS), rated on a seven-point scale ranging from 0 (extreme change) to 6 (no change), giving total scores from 0 to 24 for each domain and an overall total score from 0 to 72. Other versions of the scale measure current level of functioning (Form B) and as categorized on three levels: good, limited and poor (Form C) (110,111). The SPRS has been shown to have high levels of internal consistency, with Cronbach’s alpha ranging from 0.69 to 0.89 for the three domains and reaching 0.90 for the total score (110). High levels of interrater reliability have also been reported for the total score (0.95) and for the three domains (0.86 to 0.94) (110).

Many of the scales mentioned earlier, as well as other instruments, are described in more detail on the Center for Outcome Measurement in Brain Injury (COMBI) website, located at [www.tbims.org/combi](http://www.tbims.org/combi).

## Prediction of Outcome

Prediction of outcome raises questions about both precision and values. While relatively imprecise predictions may still be useful for service planning, modeling reimbursement, or understanding factors associated with recovery, greater precision is required to use outcome prediction for individual clinical decision making and family counseling. Moreover, although many of the outcome measurement scales have levels labeled “good” or “poor,” this should not be assumed to

represent what injured individuals or their families believe are lives worth living.

The GCS is the most widely used measure of injury severity and is a primary basis for most early predictions of outcome. The total coma score when taken at 2 to 3 or 4 to 7 days postinjury is highly predictive of outcome at 6 months, as measured by the GOS (91). Scores less than 8 are usually predictive of poor outcome. Duration of PTA also is highly correlated with ultimate outcome, with PTA greater than 14 days associated with greater likelihood of moderate or severe disability (91). More recent outcome studies have suggested that PTA duration is a stronger predictor of long-term outcome than GCS (22,112,113). The rate of early recovery, as reflected in serial DRS scores, is also predictive of final outcome (114).

Multimodality evoked potentials (MEP), a combination of brainstem auditory evoked responses (BAERs), visual evoked responses (VERs), and somatosensory evoked responses (SEPs), also have been used as an early means of assessing neurologic status and predicting outcome. Greenberg et al. found that maximal recovery occurs in approximately 3 months for patients with minimal EP abnormalities, whereas severe EP abnormalities suggest that maximal recovery may extend to 12 months (115). Somatosensory evoked potentials (SEP) can predict the gross outcome of acutely injured patients (116). The bilateral absence of the median nerve SEP suggests a very poor outcome in patients that have sustained severe TBI, whereas preserved SEPs do not guarantee a favorable one (117). While there are those who may advocate the use of evoked potentials to allocate rehabilitation resources to patients with a potential to benefit, studies have shown that evoked potentials should not be the sole basis for prediction of outcome in cerebral injury, because of inadequate sensitivity and specificity (118).

Reactive pupils are associated with better outcomes than nonreactive pupils; 50% of those with reactive pupils achieve the moderate disability or good recovery range, as opposed to 4% with nonreactive pupils (119). An absent oculovestibular response, elicited by injecting ice water into the ear of a comatose patient, is an indication of severe brainstem dysfunction and poorer outcome (11). The presence of an intracranial hemorrhage (120), and high levels of creatine kinase (BB fraction, reflecting destruction of brain tissue) measured early after TBI (121) also suggest poorer outcomes. Hyperglycemia and low levels of thyroid hormones have negative prognostic significance, presumably reflecting the severity of the stress response (122,123).

The research from Glasgow and other major TBI centers strongly suggests that the bulk of neurologic recovery from acute brain injury occurs within the first 6 months. The maximal duration of the recovery period is more controversial with some researchers affirming that recovery is virtually complete by 1 year, whereas others assert that recovery can extend 2 years or more postinjury (124). It is clear, however, that certain areas of dysfunction recover more quickly than others. For example, recovery of physical abilities and functional skills such as mobility occurs rapidly, often within 3 months after injury (125). Recovery of more complex mental abilities, as

assessed by neuropsychological measures, appears more variable. This aspect of recovery has been studied in large samples in the Traumatic Coma Data Bank study (126) and in the TBI Model Systems Project (127). Impairments of attention, information processing speed, memory, and executive function have been shown to persist up to 10 years postinjury (104). Preinjury medical and psychological factors also may affect the prognosis. For example, the presence of a prior TBI or neurologic deficit is likely to slow the recovery process. Also, if cognitive or behavioral abnormalities existed before the injury, there is a greater likelihood of a slower and less complete recovery. Acquired brain damage is thought to exacerbate preexisting behavior disorders (128). Demographic factors, including education, age, and preinjury employment status have also been shown to influence outcome (22,129,130).

Multivariate models combining PTA with age, preinjury occupational status, and early physical and cognitive disability have accounted for 60% or more of the variance in employment outcome at 1 and 6 years postinjury (24,131).

There probably is no final endpoint to the recovery process; rather, the pace of recovery slows, and its scope narrows, though occasional cases of impressive late improvement occur. Even those with permanent cognitive and physical impairments can continue to learn new skills for solving particular functional problems, albeit slowly. Thus, neurologic and cognitive recovery merge imperceptibly into ongoing learning and adaptation.

## THE ASSESSMENT AND TREATMENT-PLANNING PROCESS

The rehabilitation needs of the survivor of severe TBI often begin at the emergency department but are not likely to end for many years. Although many medical conditions and physical deficits stabilize within 1 year after injury, the presence of long-term psychosocial disorders often necessitates ongoing intervention (132). One year after injury, a quarter to a third of those with severe injuries report unmet service needs, including need for assistance coping with cognitive impairments, emotional distress, and managing financial matters (133). Survivors of TBI have a continuing need for treatment and support services across the lifespan, particularly to address psychosocial difficulties (134).

### Treatment and Support Options

Many hospital and community-based services may be of help to survivors of TBI. Changes in private and governmental funding streams stimulated much growth of specialized TBI rehabilitation services in the 1980s and early 1990s, but subsequent funding cutbacks and managed care practices have reduced their availability.

Initial management takes the form of aggressive neurosurgical intervention to minimize secondary injury. The physiatrist may be called in as a consultant even when the patient is still in the ICU, to assist the acute care team in

preventing complications such as contractures, pressure ulcers, heterotopic ossification (HO), and bowel and bladder problems that may impede later rehabilitation of surviving patients, and to assist in choosing medications that minimize sedation.

A tremendous variety of treatment programs may be appropriate for a given individual at various points in the recovery process. Acute inpatient rehabilitation is typically provided to individuals who are able to participate actively in treatment, and whose array of medical, physical, and cognitive deficits precludes a safe community placement. Less intensive subacute rehabilitation may be most appropriate for those who are vegetative, slow to recover, or cannot tolerate intensive therapy. However, many such patients, even though their rehabilitation participation is limited, have intensive medical needs that are not adequately addressed in subacute facilities. A day treatment program may be provided to individuals who can be managed at home but continue to display a variety of physical or neurobehavioral problems. This type of treatment often combines extensive cognitive rehabilitation, behavior management, daily life skills training, community activities, and prevocational activities (135,136). Residential programs may be chosen for individuals who display disinhibited, aggressive, or self-abusive behavior that cannot be managed at home. Such programs aim to reduce inappropriate behaviors and teach more effective means of communication and social interaction, through contingency management and/or pharmacological intervention (137). Transitional living programs assist individuals who have mastered basic ADLs and social interaction skills to live increasingly independently in the community. Typically, the brain-injured person lives in a supervised group home or apartment setting and is given instruction and increasing responsibility in skills needed to live independently (e.g., cooking, cleaning, money management, community mobility, job seeking), with fading of supervision over time. The final goal for many individuals is return to work, most typically through job coaching and supported work, funded by state vocational rehabilitation services.

Many clients with TBI have difficulty applying knowledge gained in one setting to related problems or different environments. In such instances, it is particularly important that the independent living and vocational training be given in the actual community or on the actual job that the individual will be attempting. Some postacute programs deliver community-based services, actively involving the client and family in goal setting and delivering most therapy in the relevant community setting in order to maximize the client's motivation and engagement in the rehabilitation process and the durability of outcomes (138).

Telerehabilitation is an emerging facet of service provision that may allow for more accurate assessment and treatment planning in the homecare context, and may allow rural patients to receive services from specialized TBI rehabilitation centers (139,140). As one example, a randomized trial comparing the effects of scheduled telephone intervention after discharge from acute inpatient rehabilitation to usual postdischarge care

found a positive impact on 1-year outcomes of this relatively low-cost intervention (141).

During the long rehabilitation process, a case manager may follow patients across multiple treatment services, providing crucial coordination and social support. This type of case manager serves as a liaison among the patient, family, and service providers and gathers medical records, arranges for medical visits, screens programs and facilities, and helps coordinate admission and discharge. With the advent of managed care, intensive case management may be even more crucial although, as noted earlier, it is less often provided (142).

Unfortunately, in many regions, these and other needed services are either unavailable or difficult to access due, in part, to the rapidly evolving changes in health care financing noted previously (143). This calls for creative financing strategies, assisted by case managers, along with advocacy efforts to expand the range of available services. Some states have developed Medicaid waiver programs that extend the array of available services, through the use of public funds (144,145).

### **Evidence for the Effectiveness of TBI-Specific Services**

As in most areas of rehabilitation, there is currently insufficient evidence for the efficacy of the services discussed earlier (146,147). However, observational data and randomized pilot studies do provide some evidence to support the impact of comprehensive systems of care for TBI, particularly in the postacute period (136,148,149). One of the few randomized trials comparing an organized program of cognitive rehabilitation to a limited home program failed to find an overall treatment effect, but did find superior outcomes for the cognitive rehabilitation program, for the more severely impaired subgroup (150).

### **Patient Assessment and Treatment Planning**

Standards of care and practice for the management of acute and postacute care of persons with TBI have been promulgated by organizations such as the American Association of Neurological Surgeons (56), the Commission on the Accreditation of Rehabilitation Facilities (CARF) (151), and the American Congress of Rehabilitation Medicine (152). Rehabilitation standards emphasize a team model to promote coordination and information sharing across therapeutic disciplines, since a specific cognitive impairment may interfere with the performance and retention of a mobility, communication, or ADL skill. Similarly, disruptive behaviors and lack of initiation cut across all therapy domains. Each of these problems requires the development of a unified team view of the patient's deficits and needs and the creation of a unified treatment plan.

When a patient enters a rehabilitation service, an initial assessment is needed to guide treatment planning. The goals of this assessment vary with time since injury. Early clinical assessment usually is aimed at defining broad functional areas in need of treatment (e.g., impaired mobility, memory deficits). Ideally, these areas are guided by an assessment of

the injured person's lifestyle, needs, and personal and family goals. As the pace of recovery slows, and discharge to home or another facility approaches, therapy focuses more intensely on the specific skills and behaviors that will be prerequisites in the new environment (e.g., toilet transfers, learning a daily schedule). Assessment also depends on injury severity. It is focused more on physical function and basic sensory processing in the severely impaired and on cognitive, social, and vocational function in the mildly impaired.

Discipline-specific assessments must be melded into a patient-oriented assessment for treatment-planning purposes. Typically, severely injured patients have a large number of medical, physical, cognitive, and behavioral impairments. Therefore, the team must develop priorities for treatment, framed in terms of long- and short-term goals, based on the needs and priorities of the patient and family, as well as such factors as estimated length of stay, functional importance of each impairment, age and developmental stage, and prognosis for improvement. As time passes, the goals become more specific and functionally oriented, such that "the patient will have increased ROM in all joints" becomes "the patient will have adequate hip flexion for erect sitting throughout the day." Identification of the patient's physical and cognitive strengths can also be very helpful in determining the best way to circumvent specific deficits. Goals being addressed by a single discipline must ultimately be shared by the team. For example, a communication strategy designed by a speech pathologist should be carried out by nurses, other therapists, and family to promote generalization of the skill.

Treatment planning also must consider the ICF (99), and its hierarchy of body structure and function, activity, and participation, and must choose at which of these levels to intervene. For example, it may be concluded that a patient's ambulation *activity limitation* is related to *limitations in body structure and function* in the form of limited range of motion, abnormal tone, weakness, impaired balance, reduced proprioception, and disordered attention. Clinicians then must choose whether to try to address each of these impairments to improve ambulation, or whether to assess the patient's mobility skills in a motorized wheelchair instead, which would be an *activity-level* intervention.

A neuropsychological assessment may be important in identifying intact cognitive skills and clarifying cognitive mechanisms responsible for various behavior and skill deficits. In the severely impaired patient, formal testing may be impossible; however, the neuropsychologist's observation of the patient may still be helpful. Higher-level patients should receive formal testing of such core cognitive areas as attention, learning and remembering, language comprehension and production, visual perception, planning, reasoning, and organization. It should be kept in mind that the results of formal neuropsychological testing have limited predictive ability for real-world function (153). Thus, patients' skills also should be assessed in naturalistic settings. Moreover, it must be understood that results obtained soon after injury only give an indication of current strengths and weaknesses. Reassessment after

longer periods is important to provide a clearer indication of cognitive difficulties that may be more lasting.

## SPECIAL SUBPOPULATIONS

### The Vegetative State

About 20% of survivors of severe TBI remain unresponsive 1 month after injury. After 2 to 4 weeks of unconsciousness, coma evolves into the vegetative state, a condition of wakeful unresponsiveness that is characterized by the presence of spontaneous sleep-wake cycles but absence of cortical activity as judged behaviorally (154).

Patients who are vegetative 1 month postinjury still may experience substantial recovery, but their chances of doing so diminish over time. Of patients who are vegetative at 1 month, there is approximately a 50% chance of regaining some degree of consciousness within a year and approximately a 28% chance of improving to a level of independence (155).

Patients continue to emerge from the vegetative state following trauma for at least a year, with rare individuals showing recovery of consciousness even later (little research is available for follow-up periods greater than a year), but nearly all are severely disabled if their emergence is this delayed (156). The term *persistent vegetative state* has been used extensively in the literature, but without consensus on its definition. It has been suggested that this term be abandoned because it confuses diagnosis (vegetative) with prognosis (persistent). Emergence from the vegetative state following nontraumatic injuries (such as cardiac arrest) is far less likely overall, and very few patients emerge beyond 3 months postinjury (155). This suggests that patients with traumatic injuries complicated by substantial secondary anoxic injury are also likely to have a poorer prognosis than those with uncomplicated trauma.

The following factors have positive prognostic significance for emergence from unresponsiveness: young age, reactive pupils and conjugate eye movements, decorticate posturing rather than decerebrate or flaccid states, early spontaneous eye opening, absence of ventilator dependence or hydrocephalus, shorter time between injury and rehabilitation admission, better scores (within the vegetative range) on the DRS, and more rapid early functional improvement (157–159). Unfortunately, no set of prognostic variables is precise enough to guide early clinical decision making. The life expectancy of those who remain permanently vegetative is not precisely known, but one study of patients in vegetative states of mixed etiologies revealed that almost 75% had died within 5 years (160). Similarly, TBI survivors with severe mobility impairments (though not necessarily vegetative) have a reduced life expectancy due primarily to cardiovascular disease, respiratory disease, choking, and seizures (161).

The minimally conscious state (MCS) refers to individuals who show some evidence of awareness in the form of visual tracking and/or motor behavior that is nonreflexive and contingent on environmental events (e.g., intermittent following of simple commands, replicable pulling out of tubes) but who

do not consistently follow commands or communicate intelligibly (162). The MCS, like the vegetative state, can be a transitional state on the way to greater recovery or it can be the permanent functional plateau (163). Misdiagnosing patients who are in the MCS as vegetative may occur more than 40% of the time, highlighting the need for rigorous diagnostic assessment (162,164).

Initial coma in TBI probably reflects disruption of brainstem-alerting mechanisms, often with relative preservation of higher brain structures. Brainstem-alerting mechanisms tend to recover with time, however, resulting in return of the sleep-wake cycle. Thus, a vegetative state of long duration generally includes extensive damage to subcortical white matter in higher brain regions, including the thalamus (165,166). Akinetic mutism and the locked-in syndrome may be confused with the vegetative state, but akinetic mutism generally involves damage to the medial frontal lobes, and hypertonia and posturing are absent. The locked-in syndrome generally results from a bilateral pontine stroke, and there is evidence of preserved consciousness and communication through eye movements (167,168).

Establishing emergence from the vegetative state can be done clinically, by observing for volitional responses to the environment, such as following commands, orienting visually to salient objects, attempting to remove tubes and restraints, and the like. Essentially, any behavior that is nonstereotyped and that indicates some evaluation of environmental stimuli is evidence of emerging consciousness. A formal and quantitative assessment strategy is an absolute requirement in working with vegetative and minimally conscious patients; without this, team and family members will disagree about whether or not evidence of consciousness is present and whether improvement is occurring. Several standardized scales are available for objectively grading responsiveness in vegetative and minimally conscious patients (169–172), although only the Coma Recovery Scale-Revised (169) incorporates items that explicitly mark the boundary between VS and MCS. In addition, the principles of single-subject experimental design can be used to answer important clinical questions in individual patients, such as whether they can see (173), follow commands (174), or reliably use a yes/no signaling system; or whether they respond to therapeutic medications (175). Assessment should take place repeatedly and at various times of day because patients may respond inconsistently, particularly as they are first emerging from the vegetative state. When family members report observing volitional behavior that has not been witnessed by staff, individualized assessments of the relevant behaviors can be conducted. Family members may overinterpret reflexive or coincidental behaviors, but staff members may fail to elicit the patient's best performance. Definitive assessment of the vegetative state must await withdrawal of potentially sedating drugs and ruling out peripheral sensory and motor deficits (e.g., blindness, deafness, extensive polyneuropathy) (164,176).

The possibility that patients who appear vegetative may have some degree of consciousness that is not reflected in observable behavior has been explored recently using functional

imaging and event-related potential (ERP) methods. These studies suggest that there exist patients who are capable of following commands to engage in specific mental activities that can be detected physiologically, even though they cannot produce observable behavioral responses (177,178). It is not yet clear how many patients classified as vegetative may be conscious as assessed by more subtle methods, or whether such patients have a better prognosis for the emergence of functionally useful behavior.

Many treatments have been attempted for patients who are in the vegetative state, but none has been subjected to an adequate controlled clinical trial. The pathologic heterogeneity of unresponsive states makes it unlikely that one treatment will help all affected people. Deep brain electrical stimulation of the mesencephalic reticular formation or nonspecific thalamic activating system has been reported to improve the clinical status in some vegetative patients, but small heterogeneous samples and early treatment make it difficult to rule out spontaneous recovery (179–182). A more recent report of late recovery of a patient in MCS after thalamic electrical stimulation does not appear attributable to spontaneous recovery (183). Dopaminergic pharmacologic treatments, including L-dopa, bromocriptine, and amantadine, also have been reported to be of help (184–187). Since all these treatments primarily augment ascending arousing influences, they would seem unlikely to benefit patients with extensive cerebral lesions. Coma stimulation (involving the systematic and frequent provision of sensory stimulation to all sensory modalities) has been widely advocated (75), but studies on it, like those on the pharmacologic agents, suffer from serious methodologic flaws, which have been summarized in review articles (188,189). Large, multicenter clinical trials will be needed to definitively assess the value of early treatments designed to improve recovery, because of the confounding and variable effects of spontaneous recovery. However, such trials are fraught with practical and ethical challenges, particularly when they involve a placebo treatment (190). A number of case reports have been published in which patients who had been vegetative for several years after traumatic or anoxic injuries paradoxically regained consciousness following the administration of a single dose of zolpidem, and whose consciousness could be maintained by repeated dosing of the drug (191). The mechanism of zolpidem response is currently under investigation. The proportion of VS patients capable of responding to zolpidem is unknown but appears to be small (192).

In the absence of definitive treatments to alter the prognosis in the vegetative state, the main goals for rehabilitation are to optimize medical stability, preserve bodily integrity, and objectively define the patient's current sensory and cognitive capacities with measures that can be monitored for change over time (156,176). This includes screening for adverse medical events such as undiagnosed seizures, hydrocephalus, and endocrine disorders. Attempts to optimize pulmonary hygiene and maintain skin integrity are also essential. Aggressive treatment of hypertonia and contractures is warranted early because they predispose to skin breakdown, interfere with positioning, and

are costly and time consuming to manage in the chronic stage. Finally, sedating medications should be avoided until the prognosis has declared itself. This includes a variety of antispasmodic, anticonvulsant, antihypertensive, anticholinergic, and antihistaminic agents that may have subtle cognitive effects in susceptible patients.

Regular evaluation with a quantitative assessment scale should be carried out. This will reveal subtle improvement that should lead to updated treatment plans, deterioration that should lead to further diagnostic evaluation, or no change, which should lead to family counseling about prognosis and planning toward home or chronic care placement. When a patient remains permanently vegetative, or when a patient remains minimally conscious but has left a specific advance directive, the possibility of forgoing further medical treatments and even life-sustaining fluid and nutrition may be discussed with the family after careful review of local legal guidelines relevant to this area and any institutional policies and ethical guidelines relevant to end-of-life determinations. However, as mentioned, a small number of vegetative or minimally conscious patients may continue to improve over several years, making the determination of permanence more difficult (193).

### Mild TBI

At the other end of the spectrum from unresponsive states is the patient with mild, or minor, TBI (MTBI), which may occur with or without impact to the head. This is generally defined as a TBI with the following characteristics:

- Loss of consciousness, if any, 30 minutes or less
- PTA 24 hours or less
- Initial GCS 13 to 15
- No focal neurologic deficit
- Negative CT and/or MRI

The initial symptoms of the cerebral injury may be difficult to disentangle from those of the common coincident injuries to the scalp, neck, and peripheral vestibular apparatus (194). Acute complaints after MTBI typically fall into three symptom clusters (195):

- Cognitive: difficulties with attention, speed of information processing, and memory
- Affective: irritability, depression, anxiety
- Somatic: headache, dizziness, insomnia, fatigue, sensory impairments

Headaches are the most common and persistent symptom and the symptom that most strongly differentiates those with mild TBI from trauma controls (196). These symptoms clear within the first few weeks or months postinjury for the majority of patients. Group studies have generally revealed impaired speed of information processing in the early hours or days after injury, but no decrement, or only modest or transient decrement, on neuropsychological measures for individuals with MTBI compared to uninjured controls beyond the first 2 weeks after injury (197). For a proportion of individuals (15%

to 25%), however, difficulties persist and are associated with social and vocational failure seemingly out of proportion to the severity of the neurologic insult (197). The etiology of these persistent complaints (often termed *postconcussion syndrome*, PCS) has been elusive and remains controversial. Premorbid factors such as substance abuse, psychiatric disorder, and age have been implicated but do not explain all cases of persistent disability. The presence of other stressors, preinjury psychological problems, being a student or being in a demanding occupation, being injured in a motor vehicle accident and/or having neck or back injury have also been associated with poorer outcomes (196,198). The idea that pending litigation or financial gain accounts for PCS has not been confirmed (195). In one SPECT study, MTBI patients with unusually persistent disability showed hypoperfusion in the anterior mesial regions of the temporal lobes (199). There is probably no one cause of PCS; premorbid variables, idiosyncratic neurologic vulnerability, and psychological reactions to acute symptoms may all be found to play roles.

The treatment of MTBI should include patient and family education about the typical symptoms and their time frame, and guidance on how and when to resume preinjury activities. Patients with persistent symptoms may benefit from psychotherapy (200), pain management protocols (201), or holistic community reentry programs offering these components along with education, vocational counseling, and group support. Many of the somatic symptoms are responsive to interventions that can be provided by an experienced physical therapist in conjunction with judicious use of medications. Therapeutic interventions may include vestibular habituation exercises (202), Rocabado exercises (203), myofascial release, trigger point injections, nonsteroidal anti-inflammatory medications, and muscle relaxants. For more extensive information, the reader is referred to more detailed publications on this aspect of brain injury (197,204–206).

Prompt diagnosis and treatment of “concussion” in sports related injuries has received increased public awareness. Practice parameters have been established by a subcommittee of the American Academy of Neurology and recommendations were also derived from the Second International Conference on Concussion in Sport (207,208). A Standardized Assessment of Concussion was developed to provide a sideline evaluation that could be performed by nonphysicians (209). Computerized neuropsychological tests have been developed for more standardized evaluation and to provide baseline data to which subsequent postinjury data can be compared (210,211).

### TBI in Children and Adolescents

Children and adolescents are a high-risk group for TBI, with etiologies varying by age group. Falls and child abuse are over-represented among infants and toddlers, accidental injuries and motor vehicle accidents in school-age children, and injuries due to violence and risk-taking behavior among adolescents.

The management and sequelae of TBI in children and adolescents are very similar to those of adults, but there are a number of issues that are specific to children. On the

one hand, it may be challenging to disentangle neurological recovery from normal growth and maturation. On the other hand, young children may appear to have minimal deficits after TBI, since the skills expected of them are minimal, only to reveal increasing developmental lags as they mature. Because “independence” is not expected of healthy children, many children with TBI are sent home without rehabilitation services, with their parents providing the assistance needed to function safely (212).

Although it has been estimated that 20,000 children and adolescents reenter school each year with significant disabilities related to TBI, surveys of special education services estimate that only about 12,000 of the more than 5,000,000 U.S. special education students receive services due to a TBI (213). This discrepancy may have several sources. Children already receiving special education services, particularly those with ADHD, are overrepresented among those injured, and they may retain their original etiology’s label; children may “grow into” their educational disability without the educational system recognizing their prior injury; and some school systems keep records by educational needs rather than etiology (212,213). Policy recommendations for improving special education services for this population have been published (213).

Problems with attention and concentration appear to be among the most frequent sequelae of TBI in children, as they are in adults, occurring in up to 50% of survivors, although as many as 19% of those injured carried a premorbid label of ADHD (5,36). Learning and memory difficulties are also relatively common in those with severe injuries (5). Language impairments have also been reported in children injured in the preschool years (214). In children with severe TBI, injury to the frontal lobes may result in executive dysfunction (215). In general, many children with mild injuries make a good recovery. Children with severe injuries show the most persistent cognitive impairments, with those injured prior to age 8 showing less recovery than those aged 8 to 12 years (5). This is not consistent with the premise that younger children show increased cerebral plasticity in the face of injury, but rather suggests there are periods of increased vulnerability (216). TBI may also have important effects on emotional adjustment in children and adolescents, with depression, dysthymia, and anxiety disorders among the most common new problems (36). In a study of college students with a history of mild TBI, intellectual impairments were not found, although the students with prior TBI had increased levels of subjective distress in several subscales of the Symptom Checklist-90—Revised (217).

Family function also has a significant influence on outcome following pediatric TBI (4), and there is also reason to be concerned about the impact of the child’s injury on the family. In particular, it has been suggested that siblings of children with TBI-related disability may experience adverse impact themselves, including greater psychopathology, depression, or reduced emotional well-being and more negative relationships (218).

The preponderance of data suggests that pediatric TBI is underreported and underrecognized in its importance. A

high proportion of children with a history of TBI are likely to present with educational special needs, cognitive problems, and psychological/behavioral problems. The fact that some of these children had such problems premorbidly, coupled with the delay between injury and appearance of the problems, may contribute to their underrecognition. Thus, it appears crucial that children with significant TBI be identified and tracked so that the relevance of their TBI to future problems and needs does not go unnoticed.

### **TBI in the Elderly**

As discussed previously, the incidence of TBI is high among the elderly, with up to 86% of TBIs in those over 65 due to falls (219). Although mortality at a given level of severity is higher among the elderly than among younger individuals, there is also some evidence to suggest cognitive impairments are more severe and functional outcomes poorer, in those who are older (127,220). Considerable controversy exists about the prognosis for functional recovery among elderly survivors, due to the fact that many older patients with TBI were already suffering from functional decline at the time of the injury, and to the fact that those elderly patients admitted to rehabilitation facilities are a highly selected group. Research that avoided this selection bias by enrolling elderly patients in acute care, found that GOS scores of moderate disability, or good recovery never occurred in those with GCS scores less than 11 (221). This was true even among the subgroup with mild original injuries and subsequent deterioration to lower GCS scores. Though it appears likely that the functional prognosis for elderly patients is, indeed, worse than for younger ones, there is also a concern that this may contribute to a self-fulfilling prophecy, in which elderly survivors of TBI are not given the same rehabilitation opportunities as their younger counterparts.

Understanding the rehabilitation problems and needs of the elderly presents some of the same challenges as those seen in the pediatric population. In a retired population, what are the appropriate standards for community integration? If the normal developmental sequence is for an increasing prevalence of disability and need for assistance with aging, how does one assess the outcome of the rehabilitation process against this moving functional target? But, unlike children with TBI, whose parents are already in the role of caregiver, elderly survivors of TBI may have few support options. A spouse may already have died or be too frail to provide the necessary care, and adult children, if any, may be unwilling or unable to provide sufficient assistance. In the absence of family and community supports, therefore, a nursing home destination may seem to be a foregone conclusion, further eroding optimism about the cost effectiveness of aggressive rehabilitation interventions.

## **MEDICAL PROBLEMS AFTER TBI**

### **Fractures**

For patients with TBI who also have long bone fractures, open reduction and internal fixation can promote early mobilization,

simplify patient care, and improve predictability of fracture outcome. Early surgical intervention may reduce health care costs and delay in mobility, but there has been concern regarding risks for potential secondary brain injury due to surgery, including the risks of general anesthesia (222). A recent article compared outcomes of patients with TBI who underwent early surgery (<24 hours after injury) or late surgery (>24 hours), including both functional and neuropsychological measures. Early surgery was not associated with poorer outcomes (223).

While most fractures are diagnosed in the acute injury period, some are not detected until transfer to rehabilitation, because of increased movement, awareness, and communicative ability as the patient improves. Details regarding the initial trauma may increase the level of suspicion for a missed fracture. The incidence of missed fractures has been reported as high as 11% in this population (223). Any unexplained swelling, deformity, or pain response should prompt evaluation for occult fracture. Fractures in TBI predispose to HO. For example, despite appropriate operative management of 23 acetabular fractures, 61% had poor outcomes because of HO (224).

## Seizures

Posttraumatic seizures and epilepsy are known complications of TBI. The risk of seizures is related to injury severity, presence of skull fractures, cortical contusion, subdural hematoma, and age (225). The risk of new seizure development is greatest in the first 2 years postinjury and gradually declines. In a population of patients who developed seizures in the first 2 years after injury, 33% of the seizures first occurred within the first month and 80% occurred within the first year (226). In another study, 86% of patients that had one late posttraumatic seizure (>7 days after injury) had one or more additional seizures within 2 years after injury, so the risk of recurrence can be high (227).

Most seizures are diagnosed clinically on the basis of focal or generalized motor activity. Patients with muscle spasms or tremors may present diagnostic dilemmas. In such cases, a routine or sleep-deprived EEG may reveal epileptiform activity. More definitive is a 24-hour EEG correlated with observations of the suspicious activity. Seizures in limbic and association areas may lead only to altered behavior or states of consciousness, presenting further diagnostic challenges.

Treatment during the first week postinjury with phenytoin or valproic acid can be effective for reducing the incidence of early-onset seizures (228,229). Long-term seizure prophylaxis is not recommended because it has not been shown to be beneficial in preventing late-onset posttraumatic seizures (230).

Carbamazepine and valproic acid have been found to be relatively free of adverse cognitive effects; their superiority to phenytoin in this regard is debated (231,232). None of these drugs is free of cognitive and physical adverse effects, however (233). These older antiepileptic drugs (AEDs) are all hepatically metabolized. Some newer AEDs are renally metabolized, which may be an advantage in certain clinical situations. It is hoped that some of the newer AEDs such as levetiracetam may not have as many deleterious side effects, but they have not been

as well studied as some of the older agents. Studies are ongoing to examine utility and safety in the TBI population (234).

There are no standard recommendations on duration of AED treatment. In view of the expense and the potential toxicity of anticonvulsants, most clinicians withdraw medications after 1 to 2 seizure-free years. Of patients with previous seizure disorders of mixed etiologies who had been seizure-free for 2 years, 35% relapsed after tapering of their anticonvulsants (235).

## Hydrocephalus

Ventricular dilation occurs in up to 40% of patients with severe TBI and usually begins to appear within 2 weeks of injury. In most instances, ventriculomegaly results from diffuse atrophy or focal infarction of brain tissue (i.e., hydrocephalus *ex vacuo*) and, thus, is a sign of primary and secondary injury but not a syndrome requiring treatment. The less common communicating hydrocephalus is generally associated with abnormal CSF pressure dynamics, causes neural dysfunction, and warrants treatment.

Unfortunately, the classic symptom triad for the diagnosis of hydrocephalus—incontinence, gait disorder, and dementia—is of little help in severely disabled patients. Failure to improve or deterioration of cognitive or behavioral function should prompt assessment with a CT scan. Flattening of the cortical sulci and periventricular lucency may support the diagnosis of clinically important hydrocephalus, but this can be a challenging determination (236). At present, there is no single test that is felt to be the gold standard in determining whether hydrocephalus is clinically significant. A recent review of the literature looked at the value of prognostic tests for idiopathic normal pressure hydrocephalus (NPH). The tap test, where 40 to 50 mL of CSF is drained and the patient is subsequently assessed to evaluate clinical improvement, was considered specific but not sensitive. A CSF infusion test to determine outflow resistance was more sensitive and specific, while prolonged drainage of CSF from a lumbar catheter may have the highest predictive value (237). The more sensitive tests may carry a higher risk of complications, especially in less medically stable or cognitively compliant individuals, which would include many patients with TBI. Even with an accurate diagnosis of clinical hydrocephalus, the prognosis for improvement from shunting is uncertain. This may be partly because the patient has other cognitive and motor deficits unrelated to hydrocephalus. Mazzini et al. suggest that patients that demonstrate a clinical deterioration may be more likely to benefit from shunting (238).

The etiology of posttraumatic hydrocephalus appears to be multifactorial. One proposed cause is the change in hemodynamics, CSF hydrodynamics, and brain metabolism caused by the presence of a craniectomy defect (239). This is of interest because there has been much discussion in the literature regarding the optimal timing of cranioplasty for patients that have undergone craniectomies, and reported improvements in function after cranioplasty have been attributed to this mechanism (240).

Patients with ventricular shunts may experience complications due to shunt failure, infection, or over/under drainage. The latter complication has been lessened through use of programmable shunt valves. Though not problem free, they have improved the ability to make minor changes in CSF flow non-invasively (241). The changes associated with hydrocephalus and shunt failure may be subtle and it is critical that the entire rehabilitation team's assessments of cognitive and behavioral fluctuations be taken into account in this evaluation.

### Cardiac Abnormalities

Cardiac complications may appear acutely, particularly in the setting of multiple trauma, and may involve direct injury to cardiac muscle, vessels, or valves, as well as the generation of arrhythmias, any of which may lead to impaired perfusion and increased secondary brain injury. Because of the multitude of potential injuries, there is no gold standard for cardiac evaluation in the setting of blunt trauma (242).

Hypertension, tachycardia, and increased cardiac output in the acute postinjury period may result from the increased release of epinephrine and norepinephrine (243). Central sympathetic hyperactivity can lead to ongoing myocardial necrosis (244). Although  $\beta$ -blockers may be considered, some medications in this class, such as propranolol, have been shown to cause cognitive impairments in hypertensive patients (245). It is unclear whether highly polar  $\beta$ -blockers such as atenolol or nadolol have fewer side effects in this population due to decreased ability to cross the blood-brain barrier.

Autonomic disturbances after brain injury may lead to dramatic increases in blood pressure and heart rate. These disturbances have been known by a number of names. More recently, the term *paroxysmal autonomic instability with dystonia* (PAID) has been coined (246). It is suggested that the diagnosis of this syndrome should be made when at least five of seven symptoms are present (fever, hypertension, hyperhidrosis, tachypnea, tachycardia, posturing, and dystonia). The etiology and treatment of this syndrome remains controversial. It has been suggested that environmental factors such as noxious stimuli may play a role in triggering the dysautonomia (247).

### Pulmonary Disorders

Multiple trauma often causes pneumothoraces, pulmonary contusions, and lacerations. In addition, adult respiratory distress syndrome, excessive fluid administration during resuscitation, and intense  $\alpha$ -adrenergic outflow may lead to noncardiogenic pulmonary edema (248). These and other problems can further compromise cerebral oxygenation.

Many brain-injured patients require tracheostomies for ventilation and suctioning. Humidified air may be delivered through a tracheostomy collar to maintain moist secretions and prevent tracheitis, and frequent suctioning may be required. Patients who initially require supplemental oxygen usually can be weaned from it by assessing pulse oximetry on oxygen and again after it has been stopped. Patients who require long-term tracheostomies but have begun to vocalize may benefit from one of the varieties of tubes that permit vocalization.

Most TBI patients eventually can be decannulated. Indirect laryngoscopy screening can be used to check for adequate vocal cord abduction and to rule out subglottic stenosis (249). In some instances, tracheal or subglottic stenosis will prevent decannulation and will require dilation or surgical management. If there is no sign of anatomic obstruction, a small-caliber tracheostomy tube will allow air to bypass the tube while it is plugged for progressive intervals. The patient is checked at the end of each interval or at any sign of distress with pulse oximetry. Once the patient has tolerated 24 hours of plugging without incident, decannulation can take place, and the tracheostomy stoma can be covered by a gauze pad or occlusive dressing until it heals. Some patients will have difficulty with decannulation because of the quantity of secretions and inability to cough them up into the pharynx. Thus, persistent suctioning is required. The tracheostomy tube itself may be an irritant that evokes secretions, however. To evaluate this possibility, a tracheal button (i.e., a small plug that keeps the stoma open) can replace the tube temporarily to see if the elimination of the tube allows patients to manage their own secretions; if not, the tube can be replaced.

Long-term survivors of severe TBI have been reported to show decreased lung capacity, vital capacity, and forced expiratory volume. The etiology of these abnormalities is not entirely clear but appears to be a combination of muscle weakness and incoordination, decreased chest compliance, and deconditioning (250). Guidelines for cardiopulmonary conditioning specifically for patients with brain injury have not been clearly established.

Pulmonary embolism is a potentially fatal end result of venous thromboembolism. Because persons with TBI who are hospitalized have many risk factors, it is not surprising that the incidence of deep vein thrombosis (DVT) is elevated in this population (251). The problem is compounded by a reluctance to use pharmacological prophylaxis because of the risk of intracerebral bleeding. The literature is too limited to allow development of a treatment standard (252). A recent survey of a group of TBI rehabilitation centers failed to identify a consensus regarding prophylaxis or screening (253).

### Hypothalamic and Endocrine Dysfunction

Hypothalamopituitary disorders after TBI may be more common than previously thought and can lead to serious medical complications (254). Any or all of the hormones that make up the hypothalamopituitary axis may be affected. Severity of TBI, as measured by the GCS, is an important risk factor. The presence of DAI and basal skull fracture is also a risk factor for pituitary dysfunction (255). Injury may result from direct trauma, hemorrhage, ischemia, or interruption of blood supply due to increased ICP or edema (255,256). Elevation of cortisol is related to increased ICP but only in the presence of an intact brainstem, and is independent of ACTH secretion (257). Onset of hypopituitarism is usually fairly acute, with one study failing to identify any new cases beyond 6 months posttrauma (258).

Chronic endocrine alterations also occur after TBI. An autopsy study of 100 brain-injured patients revealed a 62% incidence of pituitary injury (259); hypothalamic injuries coexisted in some patients. In addition, there are prominent axonal connections between orbitofrontal cortex and the hypothalamus, providing a potential mechanism for endocrine derangement without overt damage to the hypothalamus or pituitary (260). The few studies of hormone levels in survivors of TBI have found abnormalities in at least one hormone, ranging from 36% to 69% after severe TBI (261,262). Research to date has used laboratory definitions of endocrine abnormalities. Thus, the actual health impact of these derangements is unclear.

Deficiencies in growth hormone (GH) and the gonadotropins appear to be the most common anterior pituitary problems after TBI, followed by adrenocorticotrophic hormone (ACTH) and thyroid-stimulating hormone (TSH) (254). The most significant posterior pituitary disorder, diabetes insipidus, has been reported to have a prevalence of 26% in acute care (258). It should be noted that the estimated prevalence of hormonal deficiency depends on which laboratory assessment method is used. More important is the determination of when to initiate hormone replacement when a deficiency is identified. Treatment of diabetes insipidus and ACTH deficiency should be started as soon as a deficiency is identified because of the potentially severe clinical consequences (263). Loss of adequate antidiuretic hormone production can lead to life-threatening hypernatremia and hypovolemia, and deficiency of ACTH may lead to life-threatening adrenal crisis, including hyponatremia, myopathy, hypotension, and hypoglycemia. In the context of panhypopituitarism, the only hormone for which immediate replacement is not recommended is GH. This is because GH levels may normalize after other hormone deficiencies are corrected (264).

Though less dramatic, deficiencies of other hormones may lead to significant morbidity. Of particular difficulty in the TBI population is the fact that clinical signs and symptoms of deficiencies of many of the pituitary hormones mimic neurological problems often seen as a result of brain trauma. These include weakness, fatigue, cognitive deficits, decreased energy and depression (265,266). More specific consequences of hormone deficiency include: weight gain, changes in skin and hair (TSH), and sexual dysfunction and amenorrhea (gonadotropins). While amenorrhea may be transient and related to the stress of trauma, early hormone replacement therapy for hypogonadism is suggested at least for patients with multiple endocrine deficits. Persistent amenorrhea in the absence of other endocrine abnormalities may require further evaluation and, as appropriate, hormonal therapy.

Although most persons with TBI who require hormone replacement therapy have life-long needs, improvement over time is sometimes seen, so there is a need for periodic reassessment (267,268). Needs may also change during periods of medical illness or stress. In addition to traditional clinical testing, determinations regarding dosing of hormones and evaluation of efficacy of treatment can be aided by measuring clinical

elements such as fatigue, depression, quality of life, and cognitive function (263).

### Cranial Nerve Dysfunction

Olfactory nerve injuries (CN I) may accompany significant head trauma because of the delicate anatomy of the fibers exiting the cribriform plate. They are particularly likely in association with CSF rhinorrhea or after trauma to the frontal or occipital regions. The diagnosis may be missed by incomplete sensory testing including the inability of the patient to participate in testing. Objective testing of olfaction using a scratch-and-sniff odor panel is possible. Olfactory deficits may play a role in altered feeding behavior. People with anosmia are at increased risk of injury, as the sense of smell can warn one of potential dangers such as hazardous chemicals or fire.

Visual impairment may occur as spotty scotomata that differ in the two eyes, as homonymous hemianopsia, or as complete blindness. Optic nerve lesions (CN II) must be distinguished from hemi-inattention, cortical blindness, and visual agnosia. Early assessment can be done in gross terms through funduscopic examination, visual evoked response studies, and pupillary assessment. Vision and visual attention can be evaluated in severely impaired patients, using repeated presentations of colorful photographs and cards in each hemifield (173). When cooperation allows, more precise visual field and acuity testing should be performed. Neuropsychological assessment may clarify visual perceptual disorders. Information about field cuts and acuity should be shared with all team members to ensure that therapy materials are of appropriate size and placement.

Extraocular movements may be affected by damage to cranial nerves III, IV, and VI, their brainstem nuclei, or by impairment of coordinative structures in the midbrain and cerebellum (269). In addition, orbital fractures or damage to the extraocular muscles may produce disjugate gaze. Neuroophthalmologic examination may help clarify the pathophysiology of the deficit. Alternating or unilateral eye patching can eliminate diplopia. Prisms and strabismus surgery require that the patient be capable of ocular convergence to maintain binocular vision, but surgery sometimes may be appropriate solely for cosmetic purposes. CN III also contains parasympathetic fibers that control the pupillary response. This is particularly important as loss of the pupillary response ("blown pupil") may signify uncal herniation.

Temporal bone fractures may disrupt facial nerve function (CN VII) temporarily or permanently. This must be differentiated from cortical or subcortical central facial weakness. Facial weakness, when combined with corneal insensitivity as a result of trigeminal lesions, can lead to corneal ulceration; corneal lubricants or tarsorrhaphy may be indicated.

Skull fractures also may disrupt the auditory or vestibular pathways (including CN VIII). Ossicular dislocation can lead to conductive hearing loss. BAERs can be helpful in the assessment of auditory function in unconscious or uncooperative patients; however, if no response is seen at normal intensity, hearing threshold should be evaluated with increasing

intensities. Caloric testing can provide information about vestibular function. Later, standard audiologic evaluation, including speech perception, should be performed. Hearing aids or ossicular repair can be helpful in selected patients. The patient's auditory capabilities should be shared with the entire treatment team so that care can be taken to communicate in the environment and style that optimize comprehension.

Movements of the tongue, pharynx, and larynx often are impaired by severe TBI at various levels in the central nervous system (270). Evaluation of oral motor function including cough and gag reflexes and indirect laryngoscopy may help clarify the location and extent of the problem. Such disturbances will be relevant for safe oral feeding as well as vocal communication.

### Sensory Deficits

TBI can produce disturbances of any of the sensory modalities. Depending on the location and severity of the damage, these may be disturbances of basic sensation (e.g., decreased visual acuity) or of perceptual processing of that sensation (e.g., impaired visual spatial perception). Both forms of disturbance can be disabling.

Disorders of somesthetic sensation can result from damage to a variety of brain structures and may distort touch, pain, temperature, and position information. Pain syndromes may result from central injury to the thalamus, other cerebral structures, or from deranged neurotransmission between the thalamus and cerebral cortex (271).

Basic sensation can be assessed in each modality as soon as the patient is able to cooperate. Visual, auditory, and somesthetic sensory pathways can be assessed grossly earlier with evoked potential studies. The presence of normal basic sensation, however, does not ensure that the patient can form the complex perceptions needed to recognize a visually presented object, or identify a letter through stereognosis.

When patients fail at a task for which basic sensory input is intact, other causes of inability to perform can be explored. A patient recovering from cortical blindness, for example, may have full visual fields and functional acuity but may be unable to name visually presented objects. Neuropsychological assessment can help to differentiate among object-naming disorders, visual agnosias, scanning disorders, and disorders of complex visual perception (272).

There is no uniform strategy for coping with sensory deficits. Rather, treatment is planned around the severity of the deficit, strength of remaining sensory capabilities, and cognitive status of the patient. All team members should be involved in this planning because the patient's sensory, motor, and cognitive capacities all are relevant to the process.

### Heterotopic Ossification

Clinically significant HO occurs in 11% to 20% of severely injured patients, primarily in proximal joints of the upper and the lower extremities (273). The etiology of HO in brain injury is unknown. Risk factors include prolonged coma, increased muscle tone and limited movement in the involved extremity,

and associated fractures (274). A recent article also identified the presence of autonomic dysregulation as predictive of the development of HO (275).

HO may present with pain, warmth, swelling, and contracture formation but may be occult. Earliest diagnosis is possible with a bone scan, but ossification subsequently is visible on plain radiographs. Diphosphonates and nonsteroidal anti-inflammatory agents, particularly indomethacin, and radiation therapy have been used in an attempt to arrest early HO or to prevent its postoperative recurrence (273). A study of patients with early and intermediate HO found that calcium deposition occurred in the early phase, inflammation in the intermediate phase, and appearance of osteoclasts and osteoblasts in the late phase (276). This suggests that diphosphonates may be beneficial early and anti-inflammatory medication at an intermediate time, but no controlled treatment comparisons have been performed to date. A recent Cochrane review of articles that addressed acute pharmacological intervention failed to identify enough compelling evidence to support the use of medications to treat acute HO (277). Radiation has been used for prophylaxis, to treat existing HO (278) and after surgery to prevent recurrence (273). Long-term adverse effects have not yet been studied, particularly in young patients. Range-of-motion exercises are indicated to prevent ankylosis. If ankylosis seems inevitable despite exercises, it should be encouraged to occur in the most functional position.

Surgery for removal of ectopic bone should be undertaken only for clear functional goals, such as improved standing posture or ambulation or independent dressing and feeding. In general, surgery is not undertaken earlier than 18 months after injury (279).

### Increased Muscle Tone and Contractures

Increased muscle tone following TBI may reflect true spasticity (i.e., increased phasic stretch reflexes). Dystonia, posturing in response to head position and cutaneous stimulation, and extrapyramidal syndromes also are common. The mere existence of abnormal tone is not an indication for treatment. Treatment should be based on functional considerations.

### Motor Disturbances

A variety of other motor disturbances result from TBI. The diffuse nature of many injuries makes it difficult to tie patterns of motor dysfunction to specific anatomical structures. Deficits may include paralysis or paresis involving isolated muscle groups or a single limb, combinations of limbs, or the whole body, and may be caused by cortical lesions, disruption of subcortical white matter tracts, or by lower motor neuron lesions. Critical illness polyneuropathy and myopathy may be seen in more severely injured patients (280).

Disorders of balance and coordination may result from damage to the cerebellum or its connections. Patients with good muscle strength may be unable to ambulate or even sit independently because of profound ataxia. Similarly, limb ataxia may preclude self-feeding, writing, and independent ADLs.

Tremors are reported to be the most common movement disorder after severe TBI, with 5.4% of patients in one study having tremors considered to be disabling (281). Parkinsonism may be seen after a single TBI (usually severe or involving direct injury to the substantia nigra) or after repeated brain injuries as in boxers. While multiple medications have been used to treat these movement disorders, the degree of response is often disappointing.

The patient's movement abilities should be assessed by the physiatrist, physical therapist, and occupational therapist. Formal gait analysis may help reveal the specific impairments affecting gait (282), and may suggest orthotic alterations or facilitate selection of muscles for targeting with antispasticity or other treatments. Weakness can be addressed through active assistive range-of-motion and progressive resistive exercises. Ataxia is notoriously difficult to treat. A weighted walker or wrist cuffs may be of modest benefit. If ataxia varies markedly from proximal to distal joints, selective splinting or strategies to stabilize the extremity may be useful.

An attempt should be made to diagnose tremors specifically with reference to their frequency, amplitude, and occurrence during action, rest, and sleep (283). L-dopa and propranolol have been used in movement disorders such as tremors and ataxia, but functional tests should be performed on and off medication to assess efficacy in individual patients (284). Some improvement in tremor-related disability may be seen with botulinum toxin injections (285). Stereotactic surgery with radiofrequency ablation may be an alternative, but is recommended only for those with severe, disabling tremor (286). The significant risk of adverse side effects in the TBI population must be taken into account when considering this intervention. There are case reports of benefit from deep brain stimulation for posttraumatic movement disorders (e.g., (287)), but there is uncertainty about the anatomic target for stimulation, when to consider this intervention and who may be most likely to benefit. Orthoses and adaptive devices may assist weak or ataxic patients in performing functional tasks. Dexterity exercises may be used to increase manual speed and coordination.

Slowed motor responses are among the most common deficits associated with TBI and may limit self-care and employment productivity. It appears, however, that much of this motor slowness can be attributed to central processing delays rather than a motor deficit *per se* (288). There is no consensus on how to treat this generalized slowness, although there is evidence the methylphenidate improves processing speed (55,289).

Dysarthria sometimes is noted after brain injury and may be the result of either peripheral or central nervous system damage affecting motor control of the speech mechanism. The dysarthric patient may receive oral motor strengthening and breath support training to improve sustained volume. Kinematic articulography may provide more objective data regarding the nature of dysarthria and better target the area of focus for treatment (290). A recent Cochrane review did not identify any studies of sufficient rigor to support or refute the utility of therapy for dysarthria (291).

A growing body of literature supports early mobilization to aid recovery both peripherally and centrally (292). A number of automated systems for guiding motor-related therapies are in development. These computerized devices deliver movement exercises via various forms of virtual reality (VR), and make use of displacement and/or force sensors to monitor performance (293).

## Nutrition and Feeding

TBI can produce dramatic increases in basal metabolism, with catabolism, weight loss, and low serum albumin. Thus, the acutely injured patient must have increased caloric and protein intake, but the need for invasive procedures requiring an empty stomach, and the difficulty in achieving high rates of nasogastric tube feeding may interfere. While it is recommended that full nutritional replacement be instituted within the first week of injury (294), there is no consensus on how soon to consider gastrostomy or jejunostomy placement in patients who remain obtunded or lack oral motor capability (295,296). The availability of access for nutrition is not the only challenge. The gastrointestinal system must be able to move the food through the tract and absorb nutrients. In the TBI population, concern about delayed gastric emptying may be overstated (297). Gastroparesis may be a problem, especially acutely, but the medication most frequently used (metoclopramide) has the potential of slowing recovery (298), although it may be useful in decreasing reflux by increasing gastroesophageal sphincter tone (299).

Obstacles to oral feeding include both cognitive and oral motor deficits. Neuroleptic and anticholinergic medications may contribute to poor oral motor control. Attempts at oral feeding generally begin with assessment of the reflexive and voluntary components of oral motor function by a speech, occupational, or physical therapist experienced in dysphagia treatment. This is followed, if necessary, by an oral motor facilitation treatment program to decrease the latency of the swallowing reflex and improve oral motor strength and coordination.

Patients who appear to be candidates for oral feeding but who have frequent coughing or an episode of clinical aspiration may benefit from videofluoroscopy performed collaboratively by an experienced feeding therapist and a radiologist. By using different food textures and placements and head positions, it may be possible to determine a strategy to normalize swallowing. Fiber-optic endoscopy has also been found to be useful in evaluating patients with dysphagia after TBI (300). When the patient has made maximal progress in terms of food quantity and texture, the patient or family and nursing staff should be trained in the optimal oral feeding methods. Patients need to be monitored closely to determine that they are meeting their nutritional needs, especially when transitioning from tube feeding to oral intake. Altered textures, thickened liquids and injuries to the sensation of taste and smell may all affect appetite. Physical and cognitive limitations, side effects of medications, and depression may also decrease intake. Serum electrolytes and prealbumin are objective measures of hydration

and nutrition. When necessary, pharmacological interventions may be appropriate to increase appetite (e.g., megestrol acetate, oxandrolone, and dronabinol) (301).

### **Bowel and Bladder Dysfunction**

Frontal lobe lesions can impair inhibitory control over bowel and bladder evacuation, leading to urgency and incontinence. Detrusor hyperreflexia has been reported to be the predominant type of bladder dysfunction (302). Impaired mobility or dexterity, inability to communicate toileting needs, impaired initiation, cognition or behavioral deficits also contribute indirectly to incontinence, making this issue a significant one in persons with brain injury.

### **Pain**

Pain is a complex phenomenon that can complicate the rehabilitation process regardless of injury severity, and can interfere with physical activity, cognitive performance, and sleep, as well as contribute to behavioral disturbances. There are numerous etiologies for pain in this population. When TBI occurs in the context of multisystem trauma, it may be related to fractures and traumatic neuropathies and plexopathies. Complex regional pain syndrome Types I and II are also seen in this population. Other neuro-orthopedic complications such as contractures, hypertonia, and HO may generate noxious stimuli (303). Pain may also result from a host of other coexisting medical conditions commonly seen after TBI, involving gastrointestinal, genitourinary, pulmonary, renal and cardiac sources. The most appropriate treatment depends on an assessment of the source and nature of the pain. In patients who are able to describe their symptoms, assessment is similar to such assessment in non-brain-injured individuals. In minimally conscious patients, however, it may be difficult to distinguish pain syndromes from spontaneous moaning or grimacing that may have no painful etiology. Moreover, more interactive patients with memory problems may have difficulty reporting the frequency, pattern, and precipitating causes of their pain. In such instances, it may be helpful to record the behavioral manifestations (e.g., grimacing) and their relationship to potential provoking factors (e.g., ranging of a particular limb).

The range of treatment modalities available to the general population can also be applied to patients with TBI who are experiencing pain. In the setting of multiple trauma such as orthopedic injuries or in the postoperative period, narcotic analgesics may be most appropriate. Ideally, these medications should be given in standing doses or prior to therapies that incite pain rather than “as needed” since this provides better pain relief and avoids inadvertently reinforcing pain behaviors. In all cases, but especially for medications with more sedating properties, the need for appropriate pain relief must be balanced by consideration of possible slowing of the rehabilitative process (304). Nonsteroidal anti-inflammatory medications may decrease the need for narcotic medications, but have their own side effects that need to be considered. Alternative drug delivery systems, such as intrathecal infusion, may provide pain relief while decreasing the side effects compared with enteral

delivery, particularly when the patient is already being treated for spasticity with medication via an intrathecal pump.

A number of medications have been used to treat neuropathic pain, but most formal studies have involved patients with diabetic neuropathy or complex regional pain syndrome. Outcomes and side effects have not been well studied in the TBI population, so use may be governed by evaluating potential side effects in the specific clinical setting and determining efficacy once a medication is chosen. Antiepileptic medications, tricyclic antidepressants, and venlafaxine have demonstrated efficacy, whereas serotonergic antidepressants have been insufficiently studied (305,306). In addition to medications, there may be a role for physical modalities or sympathetic nerve blocks.

### **Headache**

Headache is perhaps the most common pain complaint after TBI. Interestingly, there is some evidence to suggest that it is less common among persons with more severe TBI (307). Most posttraumatic headaches (PTH) resolve within a few months although 18% to 33% of headaches may persist beyond 1 year (308). Although most headaches are not due to serious intracranial pathology, one should at least consider problems such as intracranial hemorrhage, hydrocephalus, CNS infection, or another head injury. The identification of other new neurological findings may be helpful in identifying such complications, especially in a patient with cognitive or language deficits who may not be able to provide an accurate history or description.

There are many types of PTH, and complete review is beyond the scope of this chapter. It is helpful to be aware of some broad categories of PTH, as an accurate diagnosis should lead to greater success in determining an effective treatment strategy. Musculoskeletal headaches can be broadly classified as headaches that are related to irritation of muscles, ligaments, tendons and joints such as facet joints. Interventions for such headaches may include trigger point injections, muscle stretching and strengthening, physical modalities, and medications, although it is not clear how efficacious these strategies are (309–311).

Headaches may also result from injury to nerves in the scalp damaged by direct trauma or surgery. These headaches are often described as lancinating or shooting, and may include allodynia. Headache due to occipital neuralgia is often reproducible when the nerve is palpated, leading to a characteristic referred frontal or retro-orbital pain. Diagnosis and treatment may be provided by an occipital nerve block (312). Pharmacological interventions may include medications employed for other neuropathic pain disorders. Interventions for posttraumatic migraines and posttraumatic tension headaches also generally parallel treatments seen in their corresponding nontraumatic conditions. However, one must take into account the potential cognitive effects of these medications.

### **Sleep Disturbance**

Sleep disturbance after TBI is quite common and can interfere with rehabilitation and adversely affect cognition (313).

Incidence of sleep disturbance has ranged from 30% to 70%, depending on time postinjury and defining criteria (314), with highest incidence acutely but a substantial frequency of chronic sleep problems. The initial trauma may lead to injury to neuronal structures known to be important in the regulation of sleep, such as the reticular activating system (RAS). Acutely, the environment, medications, pain, stressors, cognitive deficits, and behavioral problems may all contribute to the problem, but maladaptive behaviors and beliefs may develop and lead to persistence of the sleep problems (314). Specific sleep disorders such as obstructive sleep apnea and restless leg syndrome may have existed prior to the TBI, whether known or unknown, and may also require treatment.

Nonpharmacological management of insomnia includes environmental manipulation, relaxation techniques, and behavioral therapy. A number of medications have also been utilized to treat insomnia such as benzodiazepines, antidepressants (especially tricyclic antidepressants), and nonbenzodiazepine sedatives. All these medications have potential cognitive side effects, which must be considered in the setting of brain injury rehabilitation. Whenever sleep disturbances are suspected and treatment initiated, it is important to have objective measures to assess efficacy of the intervention(s) selected, since self-reporting may be inaccurate.

Fatigue is a closely related and among the most common complications of TBI (315,316). Like insomnia, causes of fatigue are multifactorial. There may be primary injury to neural structures such as the ascending RAS, which is very important in maintaining arousal (317). Endocrine dysfunction (266) and depression (318) can also contribute, but many patients report fatigue without an identifiable cause. Treatment is primarily focused on the identification of precipitating factors, and use of compensatory strategies such as pacing and scheduling of daily activities. Medications, especially stimulants such as methylphenidate and dextroamphetamine, have been used with mixed results. A recent double-blind, randomized, placebo-controlled trial of modafinil, a newer wakefulness-promoting medication, failed to detect a clinically significant effect (319).

## NEUROCOGNITIVE AND NEUROBEHAVIORAL DEFICITS

There is great variability in the patterns of cognitive and behavioral impairments seen following TBI. Despite this, there are certain commonalities across patients, most likely related to the typical areas of injury to the gray matter (i.e., frontal and temporal poles) and white matter (i.e., midbrain and corpus callosum). Thus, difficulty with alertness, attention, memory, planning and problem solving and abstract reasoning is very common, as are behavioral disturbances related to impulsivity, impaired initiation, and other problems of behavioral control. In the sections that follow, we review some of the most common cognitive and behavioral impairments affecting persons with TBI. Although we discuss problems separately, difficulties

labeled by clinicians and family members as “behavior problems” are often highly influenced by cognitive and perceptual disturbances. For example, comprehension deficits or slowed information processing can induce brain-injured persons to act out in frustration when their capacities are overtaxed. Variations in behavioral response may also be related to preinjury factors including age, socioeconomic status, substance use history, and personality differences. The totality of subjective experiences and personal history must be considered when evaluating problems and developing treatments for them.

Neurocognitive and neurobehavioral status may be assessed with standardized tests, as in a neuropsychological evaluation, and/ or by structured observations in real-world situations. The latter are more useful for clarifying the impact of cognitive impairments in persons who are low functioning or when status is likely to fluctuate (e.g., in the early stages of recovery). Formal neuropsychological assessment is beyond the scope of this chapter but is discussed extensively in the textbook by Lezak et al. (320).

## Impairments of Arousal and Attention

Deficits in arousal and attention are among the most widespread after TBI (288). The comatose patient suffers from profoundly impaired arousal, and many of the cognitive and emotional complaints in minor TBI are hypothesized to be attentional in nature (288). Arousal may be defined as the general state of responsiveness to environmental stimuli. Normally, arousal undergoes slow fluctuations in relation to diurnal rhythm, food intake, and activity level (i.e., tonic arousal). Arousal also can be modulated over brief intervals by demands in the environment (i.e., phasic arousal) (321). The RAS has a primary role in control of arousal, exerting its influence over diffuse cortical regions and receiving cortical inputs in return (322). Damage to the RAS plays a critical part in coma onset (50). In principle, a deficit in tonic arousal could lead to generalized impairments in responsiveness and profound slowing of information processing. Impaired phasic arousal could impair performance in cognitively demanding situations.

Attention may be considered to be the selective channeling of arousal. Attention (associated with conscious awareness) is directed to a particular set of internal or external stimuli out of the infinite set of possible targets of awareness. Attention is not a unitary phenomenon either in psychological or neurophysiological terms, and there is no precise agreement about how to divide up its component processes; at the least, the following phenomena can be distinguished (323):

- Arousal: the state of receptivity to sensory information and readiness to respond.
- Selection (sometimes referred to as *focused attention*): the ability to focus attention on particular stimuli or responses. Selection is often made on spatial grounds (i.e., selecting a stimulus in a certain location), and damage, particularly to right parietal or frontal lobes, can interfere with normal spatial selective attention (hemispatial neglect).

- Strategic (executive) control: the ability to sustain attention over time; inhibit disruption by distracting influences; shift attention in line with changing goals and priorities; manipulate information currently held in mind (referred to as working memory); and divide attention between two or more task demands.
- Processing speed: the speed at which information is transmitted within the nervous system to allow cognitive processing to occur.

Numerous brain regions appear to play a role in attentional processes. Research has particularly highlighted the roles of the right hemisphere, bilateral prefrontal and parietal cortices, the anterior cingulate, and portions of the thalamus and basal ganglia in attentional function (324). Disorders of attention may impair learning and performance in several ways. Affected patients may have difficulty focusing on any task, may be easily distracted, or may show hemispatial neglect. Attention deficits can lead to secondary decreases in language comprehension or visuospatial function because the patient's information processing is interrupted and disorganized. Inability to shift attention might be manifested, for example, in the inability to attend to task instructions and also monitor one's own performance. It has been suggested that PTA is most appropriately considered a confusional state related to attention deficits rather than a true memory disturbance (325). Similarly, frontal lobe disorders such as impulsivity and perseveration may be interpreted in attentional terms, as loss of goal-directed control over attention such that it is easily pulled or dysfunctionally fixed on irrelevant aspects of a task (326).

Exactly which of these aspects of attention are disrupted in TBI remains a subject of some controversy. There is general agreement that processing speed is reduced in TBI, but the location of this slowing in the stream of information processing is still under debate. Laboratory research shows that patients with TBI have difficulties with sustained attention (327) but

that phasic arousal to auditory stimuli is preserved even in severe injury (321). Tasks requiring divided attention appear to be particularly impaired by TBI, when both tasks require conscious control (328,329). When performing independent work in distracting environments, individuals with TBI have more off-task behavior than uninjured controls both in the presence of distractions and in their absence (330). On the basis of the many attentional studies in TBI, it appears that, other than slowed processing, most attentional complaints can be linked to strategic control of attention rather than basic arousal or selection. Strategic control, in turn, is believed to be dependent on prefrontal and limbic goals and motivations being linked to basic attentional mechanisms.

Arousal and attention are assessed best by a combination of formal neuropsychological tests and behavioral observation by all disciplines (323). It is critical to arrive at more precise diagnoses than "impaired attention" because impairments of different components of attention may have different therapeutic implications. Unfortunately, there is no consensus on what set of neuropsychological tests are most informative about attention impairments and, in particular, most useful in differential assessment. Digit Symbol and the Symbol Digit Modalities tests are sensitive to impaired information processing speed (104). Digit span forward and backward and other tests of working memory and mental control may also be useful (320,331). In less impaired individuals, tests such as the PASAT (332) and Test of Everyday Attention (333) may provide additional insight. The Sustained Attention to Response Task (SART) (334) appears to be sensitive to impairments in sustained strategic control over attention (104). In general, treatment of these disorders can be grouped in terms of pharmacologic, behavioral, and compensatory strategies (Table 24-4). Attention can also be assessed with observational rating scales such as the Moss Attention Rating Scale (MARS), which is particularly useful for patients who are too impaired for formal testing (335).

**TABLE 24.4 Treatment of Disorders of Arousal and Attention**

Component	Pharmacologic <sup>a</sup>	Behavioral <sup>a</sup>	Compensatory Strategy <sup>a</sup>
Tonic arousal	Methylphenidate <sup>b</sup> D-Amphetamine Pemoline Nonsedating tricyclics Amantadine Bromocriptine	Naps Upright position	Engage in tasks when most alert
Phasic arousal		Frequent task changes	Give alerting clues
Selective attention		Reinforce attention	Nondistracting environment
Hemispatial neglect	Bromocriptine	Graded training to attend left; prism adaptation training	Position tasks to the patient's right
Strategic control		Training in hierarchic attention skills	Simplify decision making, provide supervision, train solutions to specific problems
Processing speed	Methylphenidate	Reinforce rapid performance	Allow adequate time for responding

<sup>a</sup>Note that most of these treatments are investigational.

<sup>b</sup>All these medications may have uses beyond regulation of arousal and act on other components of the attentional network. Their respective roles are under investigation.

Many medications used for other purposes have negative effects on arousal, attention, and general cognitive function. Anticonvulsants such as phenytoin and phenobarbital, antihypertensives such as methyl dopa and propranolol, and antispasmodic drugs such as diazepam, baclofen, and dantrolene all may impair cognitive performance (336–339). Therefore, attempts should be made to withdraw such medications or replace them with less sedating alternatives (e.g., carbamazepine, ACE inhibitors, phenol or botulinum toxin nerve/muscle blocks) (340).

The role of pharmacologic treatment remains controversial. Some studies have suggested attentional benefits from psychostimulants such as methylphenidate but are subject to methodologic criticisms (small numbers of subjects, inadequate control for spontaneous recovery, and failure to specify which attentional components are being assessed) (341). A randomized controlled study suggested that methylphenidate improves cognitive processing speed, and some aspects of sustained attention, and caregiver and clinician ratings of attentiveness, while having little effect on overt orienting to extraneous distracting events (289,342). Although methylphenidate has been reported to increase seizure risk (e.g., (343)) this is not well documented, and research suggests that, on the contrary, it may have some anticonvulsant effect (344). Other dopaminergic drugs such as amantadine and low-dose bromocriptine have been reported to improve overall attentiveness, increase the ability to divide attention (345), or diminish hemispatial neglect (346). Higher-dose bromocriptine, however, does not appear to have positive effects, as judged by a randomized placebo controlled pilot study (90). Of the many drugs that have been proposed as beneficial for attention deficits, a structured evidence-based review identified methylphenidate as the agent with the strongest evidence (347). Because of the heterogeneity of attention deficits, it appears unlikely that all patients will benefit from the same drug, but selection of appropriate patients remains to be clarified. Therefore, it is recommended that, when a patient is being considered for pharmacologic therapy of attention deficits, individualized measures of the behaviors of interest be assessed both on and off the medication (175).

Behavioral retraining of attention has been advocated but is of uncertain efficacy. Some studies have suggested benefit from retraining of patients with neglect or distractibility (348–352), whereas others have failed to document changes (353–355). Moreover, few of the studies that demonstrate improvement have assessed generalization of benefits to the everyday environment. A meta-analysis of behavioral treatments for attention deficits suggests that studies involving a pretest design without an untreated control group show far more improvement than those involving a comparison to a control group, indicating that much of the apparent “benefit” of attention retraining programs results simply from repeated administration of the outcome measures themselves, combined with residual spontaneous recovery. The studies that do demonstrate greater improvement in the treatment than the control group, tend to involve attention coaching in complex tasks such as driving and ADLs rather than retraining of spe-

cific attentional capacities in isolation (356). Together, these results suggest that therapists’ energy would be better spent giving feedback about attentiveness in important real-world tasks, than supervising repetitive drills of core attentional capacities. In addition, it is important to ensure that strategies learned in a therapy environment are carried over into a variety of functional activities. Therefore, if a team member is training spatial attention in, for example, reading, interdisciplinary plans should be made to transfer the same protocol to other settings such as ambulation and ADL tasks.

In uninjured people, extensive practice of virtually any task leads to the ability to perform it with minimal attention (i.e., automatically). This phenomenon has received little study in brain-damaged patients; however, it would seem possible to deal with some attentional impairments by practicing activities to such a degree that they no longer place much demand on disordered attentional processes. Recent work by Schmitter-Edgecombe and Beglinger supports this (357).

### Impairments of Learning and Memory

Memory impairments are among the most common, persistent, and disabling of the cognitive complaints after TBI. All patients with moderate-to-severe injuries, and most with mild injuries, experience permanent amnesia for the events immediately preceding and following the injury. These intervals are referred to as *retrograde* and *PTAs*, respectively. As patients recover from the acute confusional state postinjury, retrograde amnesia typically “shrinks” toward the present (358). The final interval unaccounted for ranges from minutes to weeks or months and, in very severe cases, may “eliminate” highly salient preinjury memories, such as the birth of a child or the death of a parent. PTA is the interval of permanently lost memory following the injury; it covers both coma and the acute confusional state and is nearly always longer than retrograde amnesia. As noted earlier, its duration is commonly used as a measure of injury severity.

These permanent gaps in memory are often emotionally disturbing to patients who must reconstruct the missing interval by obtaining reports from others. Retrograde and PTAs also have legal ramifications, particularly when injuries are caused by assaults or reckless driving. Medical professionals may need to intervene with the legal system when persons with TBI are asked to testify about events they are unable to remember.

Most individuals with moderate and severe TBI suffer from ongoing deficits in anterograde memory (difficulty in storing and retrieving new information) well beyond the resolution of PTA. Because of the diffuse and multifocal nature of TBI, the learning and memory impairments typically affect multiple modalities (e.g., visual/spatial as well as verbal) and have a broad impact on “everyday memory” (359). The neural substrate of memory deficits after TBI is not fully understood. However, memory test scores have been shown to correlate with the degree of posttraumatic atrophy of the hippocampus, a limbic structure thought to play an important role in new learning (360). Given the prevalence of attentional deficits in TBI, it is also plausible that some “memory” impairment can

be attributed to defective processing of information at the time of presentation, although one study showed that challenging attentional resources at the time of stimulus encoding did *not* disproportionately affect the later recall of TBI patients (361). There is evidence that when persons with TBI are given extra learning trials, their later retrieval of the learned material can be comparable to that of uninjured controls (362). However, other research suggests that even with extra learning experience, persons with TBI fail to take spontaneous advantage of retrieval cues (e.g., categories in a word list) which boost the retrieval scores of control subjects (363). These findings imply that at least some memory deficits may be due to problems with initial acquisition, which might be overcome with extra training or rehearsal of information; and that persons with TBI might need help to notice, and use, aspects of the material that will facilitate later retrieval.

The bulk of the research on memory impairment has concerned memory for past events or past learning, that is, retrospective memory. However, a very important aspect of real-world function is *prospective* memory, which is the ability to remember to do something in the future. Prospective memory may depend partly on frontal/executive control processes that help to maintain an active goal state over time and provide “triggers” for action at the appropriate moment (364). Prospective memory is significantly impaired in persons with TBI, whether the task is framed as something that must be done at a specific time, or done in association with another activity or event (365). Real-world prospective memory problems appear as a wide variety of “failures of intention” such as forgetting to run errands or take medications, missing appointments, and neglecting to provide information or messages to others. Of the many commercially available tests and test batteries for the assessment of memory, only a few include a measure of prospective memory (e.g., the Rivermead Behavioural Memory Test) (366). More recently, the Comprehensive Assessment of Prospective Memory (CAPM) has been developed (367).

In the clinical setting, evaluation of memory impairment should not rely exclusively on test results. A functional assessment by the interdisciplinary team and careful interviewing of the family or caretakers will help to identify the environmental situations in which the disorder disrupts function, the frequency with which real-world memory problems occur, and most importantly, the cues or conditions that facilitate memory performance. As noted above, it is also important to remember that other cognitive difficulties such as in attention, language or executive function, will affect memory performance and may be interpreted or described by the affected person and family as a “memory” problem. In such cases, the memory system may actually be relatively spared, and other difficulties must be sought as the root of poor or inconsistent performance.

An influential model of memory processing that has relevance to TBI rehabilitation highlights the distinction between *implicit* and *explicit* memory. Explicit memory refers to consciously remembered material. For example, remembering yesterday’s events, drawing a picture from memory, and recounting

a conversation all involve explicit memory. In contrast, implicit memory operates outside conscious awareness and cannot be precisely verbalized; it is expressed via improved performance, for example, when new motor skills or other forms of *procedural learning* are acquired. These two memory systems, which interact constantly in normal learning, are thought to be subserved by different neuronal circuitry. Implicit memory may be diffusely represented in cortical networks, making it less vulnerable to cerebral injury than the phylogenetically newer explicit memory system, which is thought to be dependent on focal regions of the hippocampus and medial temporal lobes (368). There is evidence that in TBI, as in other organic conditions affecting memory, implicit learning is spared relative to explicit memory (369,370). A training method known as *errorless learning* has been studied in persons with TBI and other forms of organic memory impairment. Errorless learning (in which the trainer minimizes the errors committed by the trainee during the learning process) helps to bypass the need for explicit memory, which is thought to be critical for benefiting from error feedback. Without explicit memory, errors may inadvertently be learned by the more intact implicit memory system, interfering with performance. Errorless learning and related methods have been shown to be effective for helping people with TBI to learn new computer tasks, face-name associations, procedures for using memory notebooks, and other materials (371,372). The full range of tasks amenable to errorless learning, and its clinical utility in rehabilitation environments, require further exploration. Another widely used learning enhancement method, the spaced retrieval technique, involves prompting recall at gradually expanding intervals, and has been used with success, even when delivered over the telephone, to teach individuals with TBI to use external memory aids for prospective memory tasks (373).

Many other methods have been used in an attempt to remediate the memory problems experienced by persons with TBI. As there is little convincing evidence that memory can be enhanced pharmacologically (55), the most promising methods involve the teaching of compensatory strategies. For example, in a group of people with TBI who were living independently, training in the real-world application of memory enhancement strategies improved memory on objective tests as well as subjective ratings, and the improvement persisted at 4-month follow-up (374). For those with more severe memory deficits, a more commonly used approach is to train the use of reminder systems such as notebooks, planners, electronic organizers, or hand-held computers. The success of any reminder system depends partly on an individual’s awareness of memory deficits and acceptance of the need to use external strategies, both of which may be problematic. It will also be more successful if consistent with methods used prior to injury. In addition, persons with TBI may have difficulty with the executive demands of these strategies, that is, knowing *what* to record *when*, remembering to do it consistently, and using recorded information prospectively. Structured training programs in how to use compensatory memory systems may be worth the effort, however. For example, a comprehensive training regimen

to teach individuals with TBI how to use memory notebooks showed that the training had beneficial effects on measures of everyday memory function (375). Similarly, improvement in prospective memory function, as measured by diary use, was found in a program focusing on self-awareness of memory difficulties, use of a customized compensatory tool, a cueing system, and organizational strategies (376).

For the rehabilitation setting, the following summary points should be considered:

- Many persons with TBI benefit more from hands-on training of procedural skills than from verbally based or didactic instruction, although a combination of modalities may be most effective.
- The learning of persons with TBI may need to be judged by changes in performance in addition to verbal self-report, as much learning can take place of which patients are unaware.
- Errorless learning can be effective for patients with severe explicit memory impairments. It may be necessary to provide cues at each step and hand-over-hand assistance (e.g., during the training of ADL) to prevent the patient from making errors. This assistance can be gradually faded as the patient begins to initiate more of the actions correctly.
- Persons with TBI may not spontaneously recognize or take advantage of cues or aspects of the material to be remembered that will assist later recall, so therapists may need to provide explicit help in this regard.
- Memory notebooks and other organizing systems are useful for many persons with TBI. Reminder systems are most effective when they are consistent with methods used prior to injury and when the entire rehabilitation team focuses on teaching only one or two applications (e.g., scheduling appointments, recording the contents of phone calls). This allows the team to achieve more consistency in teaching “how and when to record what.” New applications can be added as the user achieves mastery of the original functions.

### Impairments of Frontal Executive Function

The mark of intelligent behavior is the ability to adapt to change, solve unexpected problems, anticipate outcomes, and otherwise cope with situations that fall outside of one’s routine. These abilities in turn require cognitive flexibility, self-monitoring, and self-adjustment of performance as well as simultaneous consideration of multiple alternatives and their probable consequences. From these alternatives, an appropriate plan of action must be selected and the intention carried to completion. Complex abilities such as these, which are necessary for adaptive human behavior, have been termed *executive functions*. There is considerable evidence linking these functions to the prefrontal cortex (364,377). TBI, which often involves damage to the frontal poles and orbitomesial cortex or their connections (378), commonly leads to disorders of reasoning, planning, and goal-directed behavior attributable to breakdowns in executive function. Depending on the nature and severity of the injury as well as premorbid factors, these

impairments may appear clinically as disorganized or tangential speech and action, a tendency to be “pulled” by irrelevant stimuli, and inappropriate interpersonal behavior (379). Lack of insight into these and other deficits and poor ability to profit from feedback are usually part of the clinical picture.

Most conceptualizations of executive function include the notion of purposeful, controlled deployment of attention and other cognitive/perceptual functions in the service of goal-directed behavior unfolding over time (380). Normal behavior falls under external control at times, as when one attends “involuntarily” to a loud noise or moving object. Behavior must be modulated, however, in the service of one’s intentions. For example, if the goal is to get to an appointment in an unfamiliar place on time, one will be more likely to attend to street signs and less likely to attend to shop windows. For such modulation to occur, emotional and motivational states must be linked to perceptual and motor systems so that the appropriate aspects of the environment may be attended to and acted on, and the irrelevant ones screened out. The breakdown of this linkage contributes to the distractibility and aimlessness of many TBI patients. Even when performing so-called overlearned routine actions such as making a sandwich or cup of coffee, persons with TBI omit steps and make errors of planning, sequencing, and object use that can be attributed to failures in this attentional control of action (381). Compared to uninjured control subjects, those with frontal lobe damage due to TBI have difficulty generating “scripts” for action plans for familiar activities such as grocery shopping, and even more difficulty implementing such plans in real time (382). Deficits in planning and goal attainment have been emphasized as central to frontal executive function in the influential research of Duncan, who conceptualizes such impairment as “goal neglect” (383).

Another important aspect of executive function is control over one’s responses to people and situations, such that some behaviors are inhibited in favor of others that are more appropriate to the context. For example, to meet certain interpersonal needs, one must judge, then select, which of many possible behaviors will achieve the goal and fit with the social milieu, and use available social feedback to check the appropriateness of one’s behavior. Individuals with TBI often lack these judgments, behaving in ways that appear inappropriate and short sighted to others, and that seem to entail “personality changes.” Thus, a male patient may behave in contradiction to his preinjury interpersonal style by exhibiting a sexually aggressive manner with a female therapist, oblivious both to her reaction and to strong cues and admonitions from members of his own family.

Remaining questions to be addressed about executive function include questions about *what* and *how many* specific cognitive processes underlie these critical functions. For example, both working memory (384) and the formation of effective plans (383) have been proposed as central operations, deficits in which may explain a variety of dysexecutive behaviors. Related lines of research have examined the relationships among seemingly disparate behavioral symptoms often

categorized as executive function disorders, such as behavioral dyscontrol, personality change, and various higher cognitive impairments. These symptoms do appear related to one another, and it may turn out that executive functions are comprised of a relatively small number of correlated factors (385).

Clinical assessment of executive function deficits is difficult for several reasons. Partly because of the uncertainty in how to conceptualize these functions, there is simply less agreement as to how they should be measured compared to (for example) learning and memory abilities. In addition, by virtue of late phylogenetic and ontological development, frontal executive functions may show more interindividual variation among healthy controls than relatively hard-wired functions such as perception and language. Thus, two people could have identical prefrontal injuries yet display different patterns of executive dysfunction (379). Because executive disorders relate to the ability to deal with novelty and change, they are difficult to see within structured tasks but must be assessed in challenging or open-ended situations. Persons with TBI may do fairly well on traditional neuropsychological tests yet show profound life disruption from executive dysfunction (364). More recently developed test procedures now provide standardized analogues to the kinds of tasks that are sensitive to executive dysfunction. For example, the Behavioural Assessment of the Dysexecutive Syndrome (BADS) is a validated battery that includes tests of planning and prioritizing as well as a rating scale to capture personality and behavioral changes affecting daily life (371,386). However, recent studies have shown that the reliability of the individual subtests and the total BADS profile score is poor (386,387). A measure which better captures everyday executive difficulties is the Multiple Errands Task, originally developed by Shallice and Burgess (388) and further developed by Alderman et al., into the MET-SV (389), with a second version adapted for use within hospital settings (MET-HV) (390). In addition, Schwartz et al. have developed the Naturalistic Action Test (NAT), a brief standardized assessment of the ability to plan and carry out everyday actions in real time (391).

Attempts to treat executive impairments have been based on one of three general perspectives (392). At one extreme, the deficits are considered to affect behavior in such a global way that they cannot be remediated. Therefore, the physical and social environment will need to be fully structured to act as “prosthetic frontal lobes” for guiding the person’s adaptive behavior. In this view, the treatment consists of determining and implementing the specific environmental conditions that will elicit and support the desired behaviors. An alternative view seeks to retrain or reinforce the separate abilities and tasks that are disrupted by executive dysfunction, for example, socially acceptable behavior or step-by-step approaches to specific situations. The third approach attempts to remediate one or more cognitive *processes* that affect executive function in a variety of contexts. These processes include “meta-strategies” such as generic problem-solving approaches (393) or techniques of verbal self-instruction (394). Some of these methods have shown promise. For example, in a study of 30 persons with TBI,

Levine et al. provided empirical support for a strategy training method known as Goal Management Training (395). A short-term trial of this method, which teaches the steps involved in defining goals, breaking them into steps, and checking one’s performance, was associated with fewer errors on cognitively demanding tasks compared to a sham-training method (practice on cognitive tasks without strategic training). However, the extent to which this method can achieve gains that are able to be generalized to improve the day-to-day executive function of individuals with TBI has yet to be established. Other methods for addressing executive dysfunction have been discussed in the clinical literature, notably by Mateer (396).

Executive impairments are of profound functional significance for severely brain-injured persons and are major obstacles to independent living, employment, and successful relationships. Until more information is available as to the effectiveness of general strategy training, particularly its impact on real-life problems, it would seem prudent not to focus exclusively on retraining abstract capacities, but to include functional activities such as planning a meal, organizing transportation, and the like.

All team members are likely to be involved in addressing these problems. The neuropsychologist may be able to suggest treatment strategies applicable to all disciplines. In addition, each therapist can assist the patient in solving the specific problems faced within tasks. For example, the physical therapist may help the patient plan how to navigate an unfamiliar route, while the occupational therapist may teach strategies for organizing a menu. Team members should be reminded that executive functions are least challenged in highly structured and routine environments such as hospitals and clinics. Thus, meaningful evaluation and treatment of these difficulties requires clinicians to avoid overstructuring patients, and to make use of real-world activities rather than limiting treatment to simulations or paper-and-pencil tasks within the clinical environment.

### Impairments of Language and Communication

Because of the diffuse nature of TBI, the classic language disorders found in stroke (i.e., aphasia) are relatively uncommon unless there is a focal dominant hemisphere lesion. More typical problems involving language and communication after TBI are related to the everyday uses of language, that is, conversation, narrative speech, and “pragmatics,” or social rules of communication. Impairments in these areas have an impact on community function and contribute to social isolation. In research on discourse and conversation, people with TBI have been shown to have difficulty selecting the amount and type of data to provide to others during exchanges of information: they may say too much, not enough, or repeat information unnecessarily (397). Ideas may be expressed tangentially, with difficulty staying on topic and reduced coherence in the narrative stream (398). Other social communication problems include overtalkativeness, difficulty initiating and taking turns in conversation, poor use of social cues emitted by the listener and impaired social perception—specifically impaired perception of

emotion in others (399). Collectively, these behaviors require others to assume most of the burden of communication during an exchange (398). Impaired conversational skills have been shown to persist for at least several years postinjury (397) and to correlate significantly with limitations in social integration (400). The La Trobe Communication Questionnaire (401) has been developed and validated as a measure of perceived communication ability, and the Awareness of Social Inference Test (TASIT) (402) as a measure of social perception following TBI.

In the clinical setting, apparent disorders of language and communication may be related to other cognitive impairments. For example, a patient may respond inappropriately to questions asked in a crowded, noisy room because of problems in auditory comprehension, abstract reasoning, and/or divided attention. For the majority of people with TBI, basic language skills will appear functionally normal to the casual observer. In a more challenging environment such as school or work, however, or in grappling with the demands of intimate relationships, communication difficulties may come to the fore and pose major obstacles to successful community integration. For instance, humor is a critically important mode of communication and social learning in adolescence. Brain-injured adolescents show impairments in interpreting linguistic humor relative to their age-matched peers, even when their scores on standard language tests are within normal limits (403).

The treatment of communication difficulties is frequently coordinated by the speech/language pathologist on the rehabilitation team. It is important that all team members, and especially family members, learn to support and reinforce the same communication methods. Patients with motor speech deficits (dysarthrias) may receive training in the use of augmentative communication devices. These may be low-tech devices such as books of pictures or letters of the alphabet to which the patient points, or computer devices and software for conversion of text to speech and vice versa (404). Pragmatic disorders of communication, such as tangentiality and wordiness, can be treated within structured groups which provide audiotape, videotape, and listener feedback. Persons with TBI can also benefit from modeling of good communication skills by other group members and group leaders. Peer group training for pragmatic communication skills has been validated empirically in a small sample by Wiseman-Hakes et al. (405). A recent study by Bornhofen and McDonald (406) suggests that aspects of emotion perception and social inference can be successfully retrained using errorless learning and self-instructional methods.

### **Agitated, Aggressive, and Disinhibited Behavior**

Problems with behavioral and affective control are common after TBI and present in different forms along the continuum of recovery. In the acute stages of injury, agitation may appear as patients emerge from coma and PTA. It has been estimated that one third to one half of patients display agitation following coma (407). In a consecutive series of 100 patients admitted with severe TBI, Brooke et al. documented restlessness in 35

and agitation (defined as aggressive or threatening behaviors) in 11 (408). The factors that predispose to posttraumatic agitation are not fully understood. One study showed that acutely aggressive patients were likely to be older and more likely to be disoriented to both place and time (409). The possible role of pain (which the patient is unable to verbalize) as well as disturbances in the sleep-wake cycle must be considered. Posttraumatic agitation typically resolves within 2 to 3 weeks of its appearance (410). Its resolution is generally paralleled by improvement in orientation and other cognitive skills as the patient emerges from PTA, lending credence to the clinical view that agitation is a “stage of recovery” for some patients (411). Acute agitation predicts longer hospital stays and lower levels of independence at hospital discharge, although these relationships are confounded to some degree by the fact that agitated patients tend to be more cognitively impaired than those without agitation (412).

Agitation may include a spectrum of behaviors, not all of which occur in all patients. Several quantitative scales have been developed for the objective assessment of these behaviors; probably the most thoroughly studied during acute rehabilitation hospitalization is the 14-item Agitated Behavior Scale (ABS) developed by Corrigan, Bogner, and colleagues (413). The ABS displays good interrater reliability (414), and rating scale analysis suggests that it measures a unitary construct despite including disparate items pertaining to hyperactivity and repetitive behavior, emotionality, aggression, and cognitive impairment (415). The use of an objective, quantitative scale such as the ABS to track recovery and monitor response to treatment is recommended for several reasons. A single patient may display a variety of behaviors at different times, such that positive or negative changes might be missed if the focus of observation is too narrow. In addition, subjective assessments of behavioral change are unreliable, and may be skewed by a few dramatic incidents or by staff members’ own emotional reactions to agitated behavior.

Management of acute agitation is a high priority in rehabilitation centers because agitation can place the patient in physical jeopardy, interfere with treatment, and cause general disruption in the therapy environment. It is frequently treated with psychoactive medication, but there are few controlled studies of the effectiveness of different medications. One such study showed that propranolol reduced the intensity of acute TBI agitation, although the number of agitated episodes did not change (410). Definitive evaluation of specific pharmacologic treatments will require a large parallel group design to control for the frequent but variable spontaneous improvement in agitation. A 1997 survey of physicians practicing in TBI rehabilitation facilities (416) contrasted the medications most commonly prescribed for agitation by “experts” in TBI rehabilitation versus by “nonexperts.” Experts stated that they prescribed carbamazepine, tricyclic antidepressants, trazodone, amantadine, and  $\beta$ -blockers, in that order. Nonexperts used some of the same medications but also listed neuroleptics (e.g., haloperidol) and benzodiazepines, two classes of drugs that the experts reported avoiding unless other medications had failed.

Benzodiazepines and other sedatives have been reported to produce paradoxical agitation (417), perhaps by making the patient less able to process events in the environment and by further impairing inhibitory mechanisms. Neuroleptics may produce akathisia that can mimic agitation (418), may produce paradoxical delusions (419), and have been associated with delayed neurologic recovery in animal models (86). Atypical antipsychotic agents have been added to the treatment armamentarium since the conduct of this survey, although studies of their comparative efficacy in TBI are lacking. Theoretical advantages include a lower incidence of extrapyramidal reactions and less complete blockade of dopamine activity that may already be subnormal due to the brain injury. The advantages, disadvantages, and indications of various classes of drugs for acute agitation have been reviewed by Mysiw and Sandel (420).

In our experience, optimal treatment of posttraumatic agitation during acute rehabilitation requires a thoughtful combination of repeated observations and assessments of behavior, carefully monitored trials of selected medications (175), and ongoing staff education and support. Since recently injured patients may move rapidly through a stage of combative and agitated behavior (408), therapy and nursing staff may need encouragement to adopt an attitude of “watchful waiting” prior to initiating medications or heavy restraints. Less experienced staff may also need education to realize that there is no medication that specifically targets single, troublesome behaviors (such as screaming) and that drugs effective for such behaviors may also inhibit other, more adaptive behaviors. For patients who may be moving through temporary agitation, treatment may simply consist of providing more intensive staffing in the short term, and removing dangerous objects from the environment. Formal therapies may need to be suspended or moved to environments with low levels of stimulation. The patient may need to be moved to a mattress on the floor to prevent injury. Environmental conditions that promote calm behavior should be observed and implemented as much as possible. A survey of nurses working on brain injury rehabilitation units identified excessive stimulation, excessively rigid rules, and interactions with staff, other patients, and family members, as the most frequent environmental triggers for agitation (421).

Patients with persistent agitation or ongoing problematic behavior, such as aggression, require more active interventions that may include medications, behavior modification techniques, or both. A behaviorally trained psychologist is often helpful in leading the treatment team in collecting and analyzing behavioral information prior to initiating treatment. Baseline data should be collected by all disciplines using an agreed-on operational definition of the problem behavior(s) or a scale such as the ABS, the Overt Aggression Scale (422), or the more recently developed Overt Behavior Scale, which covers a broader range of behaviors (423). Data should document frequency, duration, or intensity of the behavior, possible environmental factors that may have contributed to it (e.g., a difficult task, a late-arriving meal), and the consequences that followed it (e.g., a need was met, the patient was scolded). The

team should meet periodically to pool data, so it may be analyzed for patterns and factors contributing to the problem. A mood disturbance may be revealed by occurrence of a behavior at times of family contact or by episodes of crying. Cognitive impairments may be implicated if the behavior occurs primarily when the patient is working on one content area or frustrated by attempts at communication. Such hypotheses generated by the baseline data may be tested by, for example, altering the difficulty of tasks or the method of giving feedback (424). Generally, in treating persons with acute TBI, working to prevent unwanted behaviors is more effective than trying to design “consequences” that are supposed to affect the occurrence of the behavior in the future. Therapy staff may also experience much success by using redirection techniques that help the cognitively impaired patient shift his or her attention away from the source of the behavior (425). Whatever approach is taken by the team, it should be consistent across team members until reevaluation of the data can take place. Continued data collection may reveal dramatic improvement, partial response, or no improvement. Reanalysis may clarify the reasons and allow for modification of the treatment plan.

As discussed in earlier sections of this chapter, some patients with TBI do not fully recover control over volatile or disinhibited behavior; others who did not display agitation acutely may develop chronic aggression. Indeed, approximately 20% of individuals who received acute rehabilitation for a serious TBI display aggression directed toward others (compared to 4% of controls) with no significant differences in cross-sectional prevalence between 6 months, 1 year, and 5 years after injury, although individual patients showed reduction of aggression or new onset of aggression within this interval (198). Interestingly, aggression toward self, others, and objects distinguished survivors of TBI from controls, while verbal aggression did not. Studies of prison populations that reveal high rates of prior TBI provide indirect evidence of ongoing aggression that may result in encounters with the criminal justice system (426).

Chronic aggression and irritability generally have a different character from acute agitation, in that the individual is typically oriented and functioning in the community, but experiences social friction with family, friends, and coworkers that overlaps with the types of interpersonal problems displayed by uninjured individuals. For this type of problem, the Overt Aggression Scale may be the most appropriate standardized measure.

Frontal lobe lesions are associated with chronic aggression, as one might expect given the role of frontal executive systems in inhibiting behavioral impulses that are inconsistent with ongoing behavioral goals, as well as in problem solving relevant to complex social situations. Disruption of white matter connections to prefrontal cortex may contribute to similar behavioral dysfunction in individuals without focal frontal lesions. However, one should not overlook the importance of other predictors of ongoing aggression, including depression, poor premorbid social functioning, and a history of alcohol and substance abuse (427). Together, these suggest treatment

approaches that target executive function, mood, substance abuse, and social skills, may be the most logical approach to the problem.

Traditional behavior management techniques may be applied or adapted to this population. For instance, Slifer et al. reported dramatic increases in prosocial behavior and decreases in uncooperative behavior in acutely brain-injured adolescents using differential reinforcement of appropriate behavior (428). In this simple paradigm, social reinforcement (i.e., praise and attention) and other rewards are given for cooperative behaviors, while disruptive behaviors are socially ignored. Another technique, differential reinforcement of low rates of responding, rewards people for reducing the rates of unwanted behaviors such as shouting or throwing objects (429). Such behavior modification techniques do not appear to require explicit memory and thus can be used effectively with cognitively impaired patients (430,431), although it has been shown that persons with brain injury are less sensitive to response consequences than their uninjured counterparts (432). Rothwell et al. (433) and Ducharme (434) provide thoughtful discussions on how to adapt behavioral modification techniques to the particular needs of persons with acquired brain injury. Although highly structured behavior programs may be effective, there has been increasing interest in more collaborative approaches to behavioral rehabilitation that have been argued to lead to less conflict between patients and clinicians, and to be more easily integrated with the real-world consequences that might help to maintain behavioral progress (435). Indeed, a randomized controlled trial of “Natural Setting Behavior Management” (which provides behavior management training to community caregivers with maximal collaboration of the individual with TBI) found it to be significantly superior to both education and no-treatment controls in reducing challenging behaviors after acquired brain injury (436). Medd and Tate (437) also describe an empirically tested 6-week program for helping people with TBI to learn anger management techniques, following a cognitive-behavioral treatment model.

The role of medication treatment for chronic irritability and aggression after TBI remains controversial because of the dearth of well-controlled studies and the use of unvalidated measures of the problem and the response to treatment (347). Beta-blockers have the largest body of data supporting their efficacy (347,438), but positive responses to other drug classes including anticonvulsants, psychostimulants, lithium carbonate, serotonergic antidepressants, and typical and atypical antipsychotics have been reported in uncontrolled trials. It should be kept in mind, however, that the efficacy of typical and atypical antipsychotics in reducing aggression in the absence of psychosis has not been clearly established in other populations such as those with developmental disabilities (439), so it should not be assumed that these drugs are effective as a “last resort” in TBI.

### Reduced Initiation

Although challenging behaviors after TBI receive a great deal of attention, more individuals are disabled by an overall

shortage of spontaneous behavior than by problems of behavioral excess. For example, some brain-injured patients simply fail to act without extensive cueing or structure imposed from without. Many survivors after TBI may be described by clinicians and family members as “lacking in initiative,” meaning simply that when left to their own devices, they are likely to occupy themselves primarily with passive pursuits such as television, or with nothing at all. In extreme cases, patients may be able to describe a course of action verbally, and express an intention to carry it out, but still do nothing. These surface descriptions, however, may mask a wide range of underlying deficits appearing in isolation or in combination. For example, some individuals may be primarily lacking in drive and, hence, at any particular moment, there is nothing that they wish to do. Others may be motivated to establish a particular goal, but that goal decays quickly and the behavior is not carried out. Still others may establish a goal and plans for carrying on the goal, but are derailed by environmental distractions.

The ability to form an intention, link that intention to an action plan, and monitor that action plan to its resolution, appears to depend most strongly on mesial frontal regions, for example, anterior cingulate cortex (440), operating in conjunction with other aspects (such as working memory and response inhibition) of the frontal executive system, as discussed previously. While it is uncommon to see patients with lesions circumscribed to this region, various forms of initiation deficits are not at all uncommon in TBI with DAI. The concept of “apathy” is strongly related to the motivation to form an intention and has been reported as a component of many different neurologic disorders. Indeed, apathy, as measured by the Apathy Evaluation Scale, was found to be most strongly correlated with measures of executive function, and learning and memory (441). However, scores on the AES were insufficiently sensitive and specific to identify patients considered “apathetic” by global clinical impression, suggesting either problems in the psychometric properties of the scale, or lack of agreement between the constructs measured by the scale and the way the concept is interpreted by clinicians (442).

Rehabilitation of impaired initiation is challenging for a number of reasons. First, as suggested above, the failure of an individual to spontaneously carry out behavioral routines can be attributed to a wide range of underlying impairments, which may require different approaches to treatment. In addition, however, the widespread neuropathology typical of TBI may directly impact systems regulating mood and energy, drive, working memory, and executive function, such that it is difficult to attribute the behavioral deficit to a single neuropsychological cause. In planning treatment for this type of problem, team members should identify the types of real-world behaviors that fail to be carried out, and should attempt to examine, step-by-step, the processes that succeed and fail between the establishment of a goal and the failure of an action plan. Doing so may reveal specific failures in goal setting, working memory, or sustained attention that can be targeted for compensatory treatment. Effective treatment should not only lead to success on the step in question, but achievement of the larger

behavioral goal as well, or investigation of additional causes of failure should continue.

Although there are no rigorous controlled trials, the neuropharmacology of the relevant neural networks, coupled with findings in related animal and human models, suggests that noradrenergic agonists such as desipramine and amitriptyline, dopaminergic agonists such as L-dopa, bromocriptine, and pergolide, and psychostimulants may be useful in energizing behavior and supporting executive systems that help maintain it (438–440).

When the problem arises from failure to maintain an intention, or failure of working memory to keep track of progress and next-steps of a task, treatment may include physical, verbal, written, or pictorial cues for the steps involved in a task, with behavioral reinforcement for proceeding from one step to the next rather than for completion of the previous step. Structured time frames for task completion, enforced by timers, may also be of help. We have successfully used tape-recorded step-by-step instructions, in the patient's own voice, to help several patients with large right frontal lobe lesions to initiate and complete the steps of showering, dressing, and grooming without having to rely on a caretaker for these cues. Alphanumeric pagers, cell phones, and other portable electronic devices that can give automated prompts at specific times have been shown to help people with significant initiation problems to begin their daily tasks and routines in a more timely fashion (443,444). The importance of goal setting in motivating behavior should not be overlooked (445). Patients whose articulated goals promptly "decay" may benefit from a neutral alerting cue that arrives randomly and has been taught to signify that the patient should "stop and think about what you're doing" (446).

While these emerging technologies show promise in helping people with TBI become more independent in managing their routines, electronic devices are variable in their degree of "user-friendliness," and most are not specifically geared to persons with cognitive impairment. Treatment planning with assistive devices should therefore include careful assessment of the cognitive demands of operating them, as well on-going staff and/or family help with training, programming, problem solving, and technical support.

Whatever method is used, generalization across tasks should not be expected without explicit training. That is, the patient may learn to use a specific cueing system to initiate a morning ADL sequence but show no spontaneous improvement in starting homework independently. Development of flexible prompting strategies that can be used across tasks is an ideal goal. For example, if a person learns to use a hand-held computer to prompt a task sequence on the job, it may be possible to use the same device for other tasks with minimal new learning required. However, any application of a common strategy across tasks requires careful interdisciplinary treatment planning to ensure that strategies are trained, supported, and reinforced similarly across domains. Another treatment priority for initiation problems is education for both families and therapy staff. Whereas the need for physical assistance is obvi-

ous in patients with severe motor deficits, an on-going need for cognitive cues and prompts is easily misunderstood and can lead to frustration on the part of the patient who feels "nagged," and on the part of the family or staff who suspect that the patient is "lazy" or simply uncooperative.

### Awareness Deficits

It has been observed for over 100 years that some persons with acquired brain injury, including TBI, lack insight into deficits that may be obvious to others. Persons with TBI frequently seem to be less aware of cognitive and behavioral limitations than they are of physical deficits (447,448). Compared with uninjured control subjects, persons with TBI are also less able to detect and correct their errors on everyday tasks (449). For most patients, unawareness of deficit resolves to some degree over time with neurologic recovery and real-world experience of deficit areas (450). Reactive depression has been shown to increase along with awareness of one's limitations, as mentioned previously, and is associated with higher symptom reporting (451).

Unawareness of deficit may be hard to distinguish from psychological denial, which refers to conscious or unconscious refusal to admit to a problem of which one is, at some level, aware. The patient's response to direct feedback may help to sort out relative contributions of neurologic and psychological aspects (452). Regardless of its root cause, the failure to appreciate deficits creates a significant obstacle to rehabilitation efforts, and predicts poor performance in rehabilitation and poor vocational outcome (448). This may be because persons who are unaware of deficits are unmotivated to practice therapy tasks and unwilling to consider changes in employment or educational plans. In extreme cases they may see no purpose in, or need for, the entire rehabilitation effort.

The literature contains several reports of methods used to counteract unawareness of deficit. Treatment strategies may generally be classed as *educational* (based on teaching patients about deficits) (453) or *experiential* (e.g., providing systematic feedback or "planned failure" experiences) (454). Ownsworth et al. showed, in a single case with very severe TBI, that error awareness resulting in reduced errors could be enhanced in specific contexts but did not enhance awareness in other contexts or global self-knowledge of deficits (455). Ideally, feedback about deficits should be embedded in a "therapeutic milieu" that offers peer and staff support, psychotherapy, family counseling, and an emphasis on the affected person's capabilities as well as limitations (448). In our experience, it is crucial to address awareness issues at all phases of the rehabilitation process in order to avoid patient drop-out and frustration on the part of both patients and staff. We begin the education process for patients very early, so that matter-of-fact references to brain injury and accompanying deficits will gradually be accepted as part of everyday parlance. An emphasis on tasks and content areas that are both familiar and important to the patient is also beneficial in promoting recognition of the need for further rehabilitation. Staff should be encouraged to remember that unawareness is often partially an organic deficit and that

acceptance of the permanent limitations caused by TBI may take a great deal of time, patience, and support. Therapists should also avoid overemphasizing the negative in their zeal to help patients achieve “insight,” as this can sabotage the rapport needed to help the patient develop realistic awareness of deficits and their implications.

### Cognitive Rehabilitation

Given that cognitive deficits are among the most common and serious of the effects of TBI, systematic attempts to remediate cognitive functions are included as an essential component in rehabilitation programs in both acute and postacute phases of injury. *Cognitive rehabilitation* may be defined as “a systematic, functionally oriented service of therapeutic cognitive activities... directed to achieve functional changes by... reinforcing... previously learned patterns of behavior, or... establishing new patterns of cognitive activity or compensatory mechanisms for impaired neurological systems” (456). Several important concepts are embedded within this definition, including the idea that cognitive rehabilitation may be conceptualized as *restorative*, that is, targeted at regaining the previous skill; or *compensatory*, aimed at helping the person to deal with limitations by using new skills. Early attempts to develop restorative techniques used repetitive practice, such as memory drills, in the hope that this would improve cognition much as physical repetition can strengthen muscles. Such models have not proved very effective, and most programs now emphasize the development of compensatory strategies that are tailored to the individual and to the situations he/she will face in everyday life (457,458). Specific examples of intervention strategies have been discussed earlier.

With the growing emphasis on evidence-based practice in rehabilitation as in other branches of medicine, several major reviews of the literature have sought to determine whether, and under what circumstances, cognitive rehabilitation is effective (152,459). Evidence has been sought for both training programs targeted to specific cognitive skills, and more comprehensive or “holistic” programs in which cognitive training is combined with individual, group, and family therapies and vocational counseling/training within a therapeutic milieu (460–462). However, controlled research on cognitive rehabilitation methods is difficult to achieve for multiple reasons, and there have been very few well-controlled studies examining generalization of gains to daily life. The bulk of available evidence suggests that, for specific cognitive functions such as attention, training in skill areas that require that function, or training in compensatory strategies as noted above, is more effective than training in “generic” cognitive activities (152,356,459). The success of a given approach will also depend on the injured individual’s level of cognitive function, self-awareness, motivation, and capacity for behavioral self-regulation. Future efforts in cognitive rehabilitation may benefit in several ways from the rapid advances in information technology in the early 21st century. In addition to the potential for portable “personal reminding technology” mentioned in previous sections, researchers have begun to explore the applications of VR to

cognitive therapies for TBI with promising results (463,464). As technologies for designing and programming virtual environments become cheaper and more accessible, VR could have enormous potential for assisting with the efficient retraining of the cognitive components of complex skills such as route finding and driving. In the future, VR could even be used to create realistic social scenarios, to enable practice of interpersonal and communication skills.

## PSYCHIATRIC DISORDERS

### Depression

Depression is very common after TBI and has a major impact on functional and psychosocial outcome (465). A multicenter study of 666 patients involved in 17 TBI Model Systems found that 27% of patients, evaluated at 10 to 126 months postinjury could be considered as clinically depressed (466). A prospective study of 91 admissions for acute TBI revealed that 33% met the criteria for major depressive disorder at some time during the first year (467). Studies conducted over longer periods of time suggest that the frequency of depression increases over time, reaching its peak between one and 3 years after injury, but the frequency remains high over time even up to 30 postinjury (465,468,469). Posttraumatic depression is often accompanied by other disturbances of emotional function, particularly anxiety, which is comorbid with depression in over 73% of cases (465,467). Concomitant depression and anxiety in patients’ spouses is also reported (470).

Depression probably results from both neurologic and psychosocial factors. The DAI of TBI induces acute disruption of neurotransmitter systems. It is plausible that neurotransmitter depletion, particularly in noradrenergic and serotonergic systems, could contribute to acute depressive symptomatology (471). Jorge et al. (472) found a subgroup of “transiently depressed” patients whose symptoms cleared within 3 months. Transient depression was most often associated with left frontal or subcortical lesions. Major depression was associated with reduced gray matter volume in the lateral aspects of the left prefrontal cortex and with impaired performance on executive tasks (467), reminiscent of the association between left hemisphere lesions and depression in stroke patients (473). However, other investigators have failed to find correlations between lesion site and depression after TBI, nor does severity of the injury appear to be a good predictor of mood disorder (474).

The development of depression may be influenced by pre- as well as postinjury psychosocial factors, although these remain poorly understood. Prior psychiatric disorder is present at a higher rate than that in the general population, and those with preexisting psychiatric disorders are likely to develop the same disorder postinjury (475). Nevertheless, up to two thirds of psychiatric disorders develop for the first time after injury (465). Possibly for this reason, some studies have shown negligible effects of both personal and familial psychiatric history (476).

The diagnosis of TBI-related depression can be complicated. Silver and Yudofsky (477) enumerate the issues that must be considered:

- Medications including anticonvulsants, narcotics, and benzodiazepines can cause or exacerbate depression.
- Depression may predate the injury even if it has never been diagnosed. Premorbid alcohol abuse and injury circumstances that hint at self-destructive behavior are common indicators.
- The vegetative signs of depression, such as insomnia or hypersomnia, or decreased appetite, may be present for other reasons after TBI in patients who are not depressed. However, some vegetative signs (e.g., subjective anergia) do appear more frequently in TBI patients who also complain of depressed mood (478). The usual cognitive signs of depression (e.g., difficulty in concentrating) are useless for making the diagnosis following TBI.
- Self-report measures such as the Beck Depression Inventory (BDI) (479) and the NFI (466) may be useful screening tools for assessing the presence of varying levels of depression in persons with TBI.

The incidence of suicide after TBI has not been studied systematically; unfortunately, experienced clinicians can often cite at least a few cases. Of 111 patients followed by Klonoff and Lage (480), two committed suicide, and another two were hospitalized to prevent self-injury—a similar suicide rate to that seen in penetrating wartime brain injuries (481). In the Klonoff and Lage study, 14 patients reported suicidal ideation, but half of these had sustained their TBI via self-destructive acts. Simpson and Tate (482) studied 172 outpatients with TBI using the BDI, the Beck Scale of Suicidal Ideation, and the Beck Hopelessness Scale. Twenty-three percent (23%) of their participants reported suicidal ideation and 18% had made at least one suicide attempt postinjury.

The treatment of depression following TBI usually requires persistent application of more than one therapeutic modality. Medication, psychotherapy, and community reentry programs may all be effective, especially in combination. Group and individual psychotherapy can help survivors of TBI reestablish a sense of identity and self-worth. Comprehensive rehabilitation programs help by reestablishing active involvement in work, recreation, and social activities.

A recent evidence-based review found insufficient evidence to support development of standards for pharmacologic treatment of TBI-related depression (347). Tricyclic antidepressants, specifically amitriptyline and desipramine, and the serotonin specific reuptake inhibitor sertraline were recommended as treatment options. Silver and Yudofsky (477) provide guidelines for the use of tricyclic and serotonergic antidepressants in TBI. One reason to use caution with tricyclics, however, is their effects on seizure threshold (483). Although serotonergic medications may be safer with respect to seizures and anticholinergic side effects, they may also lack some of the positive cognitive effects reported with TCAs (484,485). Dopaminergic agonists and other psychostimulants should also be kept in mind for their antidepressant effects, particularly if the clinical

picture includes problems with attention and arousal and if the depression is not severe (486).

## Anxiety Disorders

There has been much less investigation of anxiety disorders following TBI, but these appear to occur in a significant proportion of cases (468,469,476,487). A recent study by Goodinson et al. (465) found that 38% of a group of 100 TBI patients followed up 1 to 5 years postinjury had developed an anxiety disorder postinjury. Generalized anxiety disorder was the most common diagnosis (17%), followed by posttraumatic stress disorder (PTSD) (14%). Specific phobias (7%), panic disorder (with or without agoraphobia) (6%), and social phobia (6%) occurred with similar frequency. Only one person was diagnosed with obsessive compulsive disorder (1%) and one with agoraphobia (1%). Those with preinjury anxiety (13%) were very likely to develop postinjury anxiety, but 74% of the cases developed for the first time after injury.

Like depression, presence of anxiety disorders also appears to be associated with poorer functional outcome postinjury (465). Despite this, there has been little research on the management of anxiety disorders post-TBI. Cognitive Behavior Therapy (CBT) is recommended as the first choice of treatment for anxiety disorders in the general population (488). In individuals with TBI and very severe anxiety, medication such as an SSRI may be required as an interim measure to alleviate symptoms in order to facilitate the person's response to CBT (487). However, considering the neurological vulnerabilities of the TBI population, wherever possible, psychotherapy should be considered prior to pharmacological interventions. One randomized controlled trial reported successful treatment of anxiety in six brain-injured individuals of mixed etiology relative to six wait-list controls, using cognitive-behavior therapy delivered individually, with gains on anxiety and depression measures maintained at one-month follow-up (489).

## Substance Abuse

Substance abuse is a significant problem in TBI. Even without a TBI, long-term abuse of alcohol and other drugs can affect cognitive function and lead to a host of social problems. In the presence of TBI, substance abuse not only complicates the process of recovery and rehabilitation but also has a negative impact on the ultimate outcomes of injury. The relationship between alcohol and TBI is illustrated by the fact that 35% to 50% of persons with TBI are intoxicated at the time of injury (490), and a somewhat higher proportion have a previous history of alcohol or other drug abuse. While estimates vary, a recent review of published studies reported a substance abuse history in 37% to 64% of persons enrolled in TBI rehabilitation (414). Clinical screening for alcohol abuse may be accomplished bedside using brief, relatively nonconfrontational instruments such as the 4-question CAGE (491). For research purposes or in-depth assessment, it is more appropriate to use quantitative measures of the extent and consequences of substance use, such as the Michigan Alcohol Screening Test (MAST) and the Quantity-Frequency-Variability Index (492). A composite measure using the short form of the MAST,

information on quantity and frequency of consumption, and blood alcohol level at the time of injury has reportedly been useful in identifying problematic drinkers with TBI (493). Other methods to assess intake of alcohol and other drugs include questions developed for national/international health surveys, such as the National Household Survey on Drug Abuse (494), the Behavioral Risk Factors Surveillance System (495), and the AUDIT and ASSIST questionnaires developed by the World Health Organization (496,497). Such instruments have the advantage of being referenced to a large population-based sample, which can help in determining whether intake is statistically abnormal. However it is measured, a history of substance abuse predicts poorer TBI outcomes in terms of vocational success and overall quality of life (490,498). After injury, continued substance abuse can exacerbate neurobehavioral deficits, contribute to disruption of family relationships, and further reduce the probability of return to work. Several studies have shown a decline in drinking and drug use in the first year or so after TBI (499,500), but it also appears that people tend to return to preinjury drinking and drug use patterns by 2 years postinjury (500). These are mostly young males who were heavy substance users preinjury, whereas few develop substance use problems for the first time after injury (500). There has been less research on the impact of drugs other than alcohol on TBI; there is overlap among samples, as many drug abusers also consume alcohol (414). A history of street drug use was acknowledged by one-third of outpatient TBI participants in one study; marijuana was the most popular, followed by cocaine (501). Substance abuse remains a serious problem for a significant number of persons following TBI, and rehabilitation programs must be ready to help patients address the issue either with trained staff or appropriate referral mechanisms.

The implementation and success of treatment approaches commonly used with nondisabled populations, such as the 12-step programs of Alcoholics Anonymous and Narcotics Anonymous, may be complicated by the memory, communication and reasoning deficits caused by TBI. There are published recommendations

for how to adapt these programs for TBI (502), and specialized substance abuse treatment approaches have also been developed for this population. For example, Corrigan et al. (414) describe comprehensive models for integrating substance abuse treatment into community-based TBI rehabilitation. These models emphasize patient, family and staff education, in-depth assessment, careful coordination of services, and specialized therapy techniques such as “motivational interviewing,” to help the person internalize the motivation to change substance use habits. Other researchers have emphasized the need to assess each person’s receptivity to substance abuse counseling by using questionnaires specialized for this purpose, such as the “Readiness to Change Questionnaire.” This brief questionnaire has been validated for use with persons with TBI (503) and may be especially useful for revealing the “windows of opportunity” for drug and alcohol counseling that occur relatively soon after injury (504). In a small study involving 12 TBI participants, Bombardier and Rimmele (505) found that 75% of those who received a brief motivational interview reported drinking less than one drink during a typical week at 1 year follow-up, compared to 55% of individuals who did not receive any intervention.

## PARTICIPATION IN COMMUNITY LIFE

### Concept of Task Analysis

As already discussed, many different impairments may contribute to the defective performance of important skills and, in interaction with the physical and social environment, may limit participation in social and vocational activities. To understand which impairments are responsible for specific limitations in activities and participation, a task analysis must be conducted. This involves considering the physical, cognitive, and social demands that different tasks place on the individual to clarify where task breakdown occurs. Ultimately, a clinician specializing in TBI rehabilitation must be as perceptive and knowledgeable about tasks as about patients. In Table 24-5, a

**TABLE 24.5** Some Component Processes Relevant to Mobility

Component	Role in Mobility
Range of motion	Must allow for required movements
Strength	Necessary for ambulation, wheelchair propulsion, or switch operation
Balance and postural reflexes	Necessary for safe ambulation and transfer and adjustment to sudden perturbations
Muscle tone	Must allow for effective use of strength
Visuospatial perception	Necessary for environmental navigation
Spatial attention	Necessary for awareness of both sides of space
Concentration	Necessary for maintenance of locomotion in presence of distractions
Memory	Necessary for using previous experience of routes and locations
Planning, organization, and reasoning skills	Necessary for mobility in unfamiliar environments and using public transportation
Initiation	Necessary for turning plans into action

simple task analysis has been done for a mobility skill, demonstrating that an ability that is often thought of as physical has important cognitive requirements as well. Once the task demands have been understood, there is a choice about whether to modify the task to be more accommodating to the individual, or to try to modify the individual to be more adept at the task. This choice will depend on time since injury, learning ability of the individual, availability of effective treatments for specific impairments, flexibility of the task requirements, perspective of the patient, and many other factors.

### Community Mobility

As shown in Table 24-5, community mobility may be limited by a complex combination of physical, cognitive, and neurobehavioral impairments. These interact with availability of transportation services, where the individual lives, presence of curb cuts, and so forth. Aggressive attempts should be made in the early months postinjury to improve these impairments. Purchase of permanent assistive devices should be postponed until the patient's ultimate level of physical function is relatively certain.

Many survivors of TBI lose the ability to drive because of epilepsy or visual, cognitive, or motor impairments (506). This severely limits community mobility, particularly in rural areas. Some may regain the ability to drive, but the criteria on which to base this judgment are controversial. Certain perceptual and motor tests may reveal impairments that preclude driving, but good performance in basic sensory and motor functions does not guarantee safe driving. Attention-demanding driving simulation tasks (507,508) and VR road tests (509) show promise in helping to evaluate driver safety after TBI, but further validation is necessary before their sensitivity and specificity is known. Actual road tests can also be used, though the range of traffic occurrences that will occur during such tests is difficult to control. Preliminary research suggests that some poor drivers may benefit from specific retraining (510). A small study of survivors of TBI who had completed a postinjury driving evaluation program and had returned to driving, did not reveal an elevated risk of accidents, providing some reassurance that such programs do not return drivers to the road who should not be driving (511); whether there are individuals who could be driving safely but are not able to clear the hurdles to return to the road is unclear.

### Self-Care Skills

As with mobility, ADL independence may be limited by a complex combination of physical and cognitive impairments. A similar process of interdisciplinary physical and cognitive assessment may lead to identification of particular component processes that are especially significant. Basic ADL skills such as dressing, bathing, and feeding may be improved with a treatment program aimed at three components:

- Improving salient physical or cognitive deficits such as serial casting for contractures or stimulant medications for arousal and attention deficits

- Compensating for salient physical or cognitive deficits through provision of assistive devices for physical deficits, or written or pictorial cue cards for cognitive deficits
- Retraining tasks without specific regard for the contributing deficits using behavioral training methods (e.g., breaking down into small steps, backwards chaining, errorless learning, reinforcement) (512).

Similar treatment principles are involved in addressing instrumental ADL, which generally place greater demands on executive function. Training provided in a hospital or clinic setting will need to be generalized to the home environment through family training and/or a process of home visits and home therapy.

### Social and Family Impact

Following TBI, the most obvious and disabling impairments are in the sphere of social behavior. The person with brain injury may thus have great difficulty maintaining preinjury relationships or establishing new ones. These behaviors are ultimately attributable to the interplay among neurobehavioral deficits, unique premorbid personality traits, and postinjury coping responses. Deficits in frontal executive functions, communication, and behavioral control (described in previous sections of this chapter) may particularly predispose patients to long-standing social problems. Poor performance on tests of cognitive flexibility is predictive of social withdrawal (513), as is impaired initiation (514). Reviewing the literature on social disability after TBI, Morton and Wehman (515) pointed to four recurring themes:

- Decline in friendships and social supports, leading to isolation that does not improve spontaneously
- Lack of opportunity to make new social contacts because of a restricted range of activities (e.g., unemployment, inability to drive)
- Inability to engage in preinjury leisure activities
- Depression, which further reduces social initiative and increases isolation

Unfortunately, treatment of social behavior problems is seldom completely effective. Group therapy with modeling of appropriate behavior can be beneficial and is part of most comprehensive community reentry programs for TBI. Success has been reported using structured social skills training, with videotaped feedback, in postacute patients (516). A study of a structured peer support program for persons with brain injury and their families indicated that it improved participants' overall quality of life, general outlook, coping skills and knowledge of TBI, but did not enhance level of social support received from family and friends (517). The internet has also been used as a means of providing information and social support, but its efficacy has not yet been validated (518).

Only a few investigators have systematically examined the effects of TBI on leisure and recreational participation, but they concur that TBI significantly disrupts premorbid leisure pursuits, due to residual physical and neurobehavioral

impairments (519,520). Because many do not return to work either, loss of leisure activity may be psychologically devastating. A recreational therapist can be an integral team member, performing leisure skill assessments and developing both individual and group treatments to teach new ways of occupying leisure time or adaptive methods for performing favorite pre-morbid activities.

The Clubhouse model is an innovative approach to the social isolation of persons with TBI (521). Clubhouse programs are organized around a work-ordered day (i.e., up to full-time participation), and are run by clients who have suffered TBI, with staff support. A productive social milieu with peer support and naturalistic learning and opportunities for both recreational and vocational activity are key features of such programs. Client strengths and contributions are stressed, in contrast to the “deficit” emphasis found in many therapy programs.

Numerous studies have attested to the extreme stress placed by TBI on the family system (522). An early Israeli investigation of marital adjustment 1 year after war-related brain injury found interpersonal tension within the family; feelings of loneliness, depression, and isolation in the wives; lack of sexual contact with husbands because of loss of feelings of attractiveness and personality changes; and role changes within the family (523). More recent studies from the USA and New Zealand have amply replicated these findings (470,524–526). Furthermore, the stress and family disruption experienced by caretaking spouses may be worse than that experienced by parents in a comparable role (525). Studies of the sources of family stress invariably find greater impact of cognitive and behavioral deficits than physical care needs (525,527,528). Kosciulek (529) identified five distinct and effective coping strategies used by families after TBI:

- Positive appraisal, which is commitment to seeking the positive while accepting things as they are
- Resource acquisition, or the tendency to seek help and guidance
- Family tension management, which involves open expression of feelings
- Head injury demand reduction, for example, seeking support groups or becoming involved in advocacy
- Acquiring social support from friends and relatives

Inclusion of the family in rehabilitation programs has become standard practice. Families of TBI patients feel strong needs for regular communication with staff, specific information about the injury, and honest answers to their questions (530). Perhaps in response to this, a great emphasis has been placed on individual or group family education, and, as needed, family counseling, family therapy, and support groups (531). The use of a telephone-based, social work liaison follow-up has been demonstrated to reduce caregiver burden, increase quality-of-life ratings, and enhance feelings of caregiver mastery, compared to a historical control group. Though limitations were cited in the methodology by the investigators, this may prove to be “a low-cost, nonintensive intervention [which] may offer

substantial benefits to families caring for people with brain injury” (532).

### Sexual Relationships

Disturbances in sexual function after TBI often have been noted by clinicians but have not been well studied. Sexual dysfunctions may include hypersexuality, hyposexuality, impotence, loss of feelings of attractiveness, inability to find appropriate partners, and incapacity to engage in intimate interpersonal relationship requiring the interpretation and expression of complex emotions (533).

Staff members and relatives often are dismayed by the sexual dysfunctions after TBI and have difficulty in managing these problems effectively. Rehabilitation facilities have developed sexual reeducation programs for brain-injured patients in which specific information is provided about sexual function and basic social skills in interpersonal intimacy are taught (533).

Sexual behavior most often is perceived by staff as a problem when the patient engages in overtly inappropriate behavior, such as public masturbation or continual advances toward uninterested partners. In these cases, team members often are asked to intervene to help reeducate and redirect the patient toward a more appropriate expression of sexual drive. Behavioral interventions may assist in reducing these problems.

Inadequate sexual function too often is neglected because it creates fewer problems for family and staff. However, it is a much more common problem. In a study of 208 individuals with moderate-severe TBI (69% males) 1 to 5 years postinjury, Ponsford (528) found that the majority of participants reported significant negative postinjury sexual changes, with 36% to 54% reporting a decrease in the importance of sexuality, sex drive, sexual opportunities, frequency and enjoyment of sexual activity, in addition to their ability to give their partner sexual satisfaction, to engage in sexual intercourse, to stay aroused, and to climax. The frequencies of such negative changes were significantly higher than those reported by a demographically matched control group and far outweighed the frequency of increases on these dimensions. A significant proportion of TBI participants also reported decreased self-confidence, sex appeal, higher levels of depression, and decreased communication levels and relationship quality with their sexual partner. It is likely that these changes occur as a result of both organic factors, including limbic system injury and/or hormonal disruption, and other factors including fatigue, physical disability, pain, reduced self-esteem and social skills, relationship quality, and affective change. Medications may also impact on sexual function.

It is extremely important that all potential causes of sexual difficulties be investigated and attempts made to address them. Assessing sexuality should be a routine part of the assessment and rehabilitation process, because these are not easy issues for clients to raise. Rehabilitation staff need to be willing to talk with their clients about sexual issues and have access to specialist skills for assessing and dealing with them, in the context of an understanding of the injured person's cog-

nitive limitations. The “You and Me” program, developed by Simpson (534), represents a valuable resource for staff, clients, and their families.

It is also critical for the physician to provide information regarding safe sex practices and contraception to all patients. These include mutual disease screening if indicated and use of condoms and spermicides. However, education alone is often inadequate for individuals who have difficulties with impulse control and executive function and who may be vulnerable to manipulation by others either through personal contact or through the internet. Therefore, sexual counseling should occur in the context of a full appreciation of the individual’s neuropsychological and emotional status. Communication and intimacy may be enhanced for some patients and their partners through the use of educational materials and individual and couples counseling. Some patients, particularly those with specific sexual disorders, may require the intervention of a sex therapist.

### **Educational, Prevocational, and Vocational Function**

TBI may produce significant educational and vocational disability. Numerous studies of return to work following TBI suggest that both premorbid and injury-related factors play strong roles in vocational success. Previous education, work history, psychiatric history, and substance abuse are all strong predictors of return to work (535). In addition, injury severity, cognitive impairment, and behavioral disturbances are related to reemployment (535–537). Social isolation after injury has also been negatively associated with return to work (535), but whether this reflects the coexistence of depression, lack of initiation, or poor social skills that interfere with work, or whether the social isolation is the result of loss of work-related social outlets is unclear. More than half of a group of 172 of those with moderate-to-severe TBI who had returned to work reported that their duties had changed and more than a third reported continuing fatigue, problems keeping up, and a tendency to make mistakes even 5 years postinjury (23).

Many of the same factors adversely affect school performance among individuals suffering TBI during their youth. Secondary school and college students returning to study after TBI often report difficulty keeping up with the workload, with slowed learning and increased fatigue, such that 89% report that it takes a moderate or extreme degree of effort to pass courses and many require special educational accommodations (23). However, since education, unlike employment, is an entitlement, the impact of TBI may be less obvious. Although Public Law 94-142 guarantees educational opportunities for brain-injured children, as well as other disability groups, up to the age of 21 years, the implementation of special accommodations for them varies greatly, depending on the local school district’s educational philosophy, available resources, and understanding of the problem. For the elementary and secondary school child, transition back into school can be traumatic. For this reason, it is advisable for school personnel, rehabilitation team members, and the family to help the school

develop an individualized education plan and to ensure that all teachers understand the impact of the brain injury. Once the child leaves school, further assistance will generally be required in order to facilitate exploration of vocational options.

A growing number of community colleges and universities offer educational programs tailored to individuals with brain injury. At these schools, remedial courses in basic skill areas such as reading or mathematics are provided. In other cases, supplemental tutoring may be made available. To assist with daily living needs, a group-living situation with assistance from a residential counselor sometimes is available. These modifications allow a higher-level brain-injured person to progress at a slower pace with a great deal of support and a far greater likelihood of academic success than in a typical college environment.

Vocational goals are important to many brain-injured people once they complete their acute rehabilitation. The major problem is that their vocational goals may be based on their premorbid abilities or vocation and may be unrealistic in the context of current disabilities. Some comprehensive rehabilitation programs include prevocational assessment and vocational training (538). After the patient completes a period of extensive cognitive rehabilitation, a vocational counselor designs a vocational program that usually involves work trials within the rehabilitation setting, progressing into the workplace. Another model of vocational rehabilitation after brain injury has been the supported employment approach (539,540). In this approach, the client may be placed directly into a competitive employment situation, where a job coach provides daily on-the-job instruction and guidance, advises the employer as to potential job modifications needed to maximize the client’s performance, and assists with other job-related issues such as transportation, housing, financial management, and substance abuse. The supported work model has been viewed as the most effective in returning brain-injured people to competitive employment, although there have been very few rigorous studies of efficacy. The conclusion of efficacy is based mainly on successful return to work after participation in such programs of individuals who have been previously unsuccessful (102,541).

Every U.S. state has a Department of Vocational Rehabilitation, providing any of a wide variety of services, including prevocational assessment, vocational assessment, work adjustment training, sheltered workshop training, or a supported work program. A neuropsychological assessment usually is requested by vocational counselors as an essential component on which to base the vocational plan. However, it is generally agreed that direct observation of clients in work settings or simulations is a more useful guide to vocational success and appropriate vocational goals than standardized neuropsychological testing (542). It is very important to educate the employer and fellow employees regarding the injured person’s difficulties and ways of supporting him or her. A graduated approach to return to work is generally necessary, with follow-up contact to deal with problems that may arise as time passes and work demands or fellow employees change.

## MEDICOLEGAL AND ETHICAL ISSUES

A variety of medicolegal and ethical issues can complicate the rehabilitation process. There is frequently the need to determine the competency of the brain-injured person to manage financial affairs, engage in vocational pursuits, make medical decisions (543), or provide informed consent for research participation (544). Obtaining informed consent in the rehabilitation setting for people with TBI poses its own unique difficulties (545,546) as related to the use of behavioral or psychopharmacologic restrictive procedures (547), decision making about surgical interventions or transfer to a different type of treatment program, and rights to privacy (548). Competency assessments after TBI can be complex, involving the contributions of many disciplines (549). If the court deems a brain-injured person to be incompetent, a conservator may need to be appointed to manage financial affairs or a guardian to make decisions for the person. To complicate matters, family members are often reluctant to move toward guardianship early, in hopes that the individual will recover sufficiently to remain in charge of his/her own affairs. This often leaves an ethical gray area when clinicians understand that an individual's ability to make decisions is compromised, but there has been no official determination of incompetence or appointment of a guardian. Most often, clinicians seek to involve the individual and their caregivers in such decisions, thus minimizing the importance of the exact decision-making status. However, when the individual with TBI and his/her caregivers disagree about important decisions, or when there is disagreement within a group of caregivers, formal determination of the legally authorized decision maker may become necessary. Legal determinations of competency are binary, whereas clinicians recognize the fact that capacity for decision making recovers gradually (550), and that the legal dichotomy is in tension with principles of empowerment that encourage impaired individuals to participate actively, with support, in making important decisions (551).

Another issue for many is personal injury litigation, which often results from accident cases. In this circumstance, the person with brain injury tries to recoup financially for past medical expenses, pain and suffering, and past and future lost wages. Although a large settlement can be very beneficial to the individual, it often takes 5 years or longer for a case to be settled in the courts. This produces a severe stress on the survivor and the family. Furthermore, individuals with brain injury can be their own worst witnesses because of their memory impairments and normal physical appearance, and many achieve minimal financial gain (552).

Perhaps the most dramatic ethical issues in brain injury have been raised about the treatment of patients in the vegetative or MCS. Clinicians, lawyers, and theologians have debated the rights of family members to withdraw life-sustaining nutrition for people in the vegetative state (156,553,554). Although ethical viewpoints vary, terminating artificial hydration and nutrition for an individual judged to be permanently in the vegetative state is legal in most jurisdictions. Matters

are much more complex in the MCS, since such individuals are, by definition, incompetent to make their own decisions about continuing treatments and nutrition. In principle, one could solve this problem by completing an advance directive that specified what treatments one would want in such a state. In practice, however, many individuals who are injured have no advance directive in place, and those who do have one have rarely included enough specifics that are applicable to the MCS for the courts to be convinced of their prior wishes. Though not legally binding, there have been attempts to assess the perspectives of individuals in this state on life and death issues, using repeated structured yes/no questions (555). In one case, a minimally conscious patient appeared to indicate her desire to continue to live (193). She made modest further recovery over the next several years, and as her assessments produced more clear-cut responses, these supported the validity of her earliest statements of preference. Ethical issues surrounding the permanent vegetative state have only become more complex because, as discussed previously, scientific advances have questioned both the validity of a behaviorally based diagnosis of the vegetative state, and the validity of the designation of permanence. With regard to current diagnostic criteria, for example, the report of a patient who could follow directions to engage in specific mental imagery tasks, as evidenced by fMRI, questions the ability to fully assess consciousness from behavioral responses alone (178). And the report of several "permanently unconscious" patients who regained consciousness with the drug zolpidem, undermines the notion of permanence (191). Thus, it appears that an all important ethical line between conscious and unconscious states may not be tenable in the future, requiring much more complex ethical reasoning.

Members of the rehabilitation team and outside consultants may help navigate through these complex issues. Many health care facilities have ethics committees or consultation teams, which assist in the evaluation of difficult treatment decisions. A lawyer frequently is hired to represent the brain-injured person in various types of litigation. Unfortunately, most attorneys are not knowledgeable about TBI and must be educated by health professionals. All the members of the rehabilitation team may be asked to assist in medicolegal cases, although typically the physician specialists (e.g., psychiatrist, neurosurgeon, neurologist) and psychologist (e.g., neuropsychologist or rehabilitation psychologist) are those who are asked to provide detailed records and to testify in court.

## SUMMARY

In recent decades, increased attention has focused on TBI, as one of the most common causes of disability across the lifespan. Emergence of TBI as a prominent consequence of recent international conflicts has further fueled interest in treatment and research. Research on TBI has led to a number of important advances in knowledge. The epidemiology, pathophysiology, and course of recovery have been substantially defined. Our ability to estimate prognosis has improved. The medical,

physical, cognitive, and behavioral sequelae of TBI have been more clearly identified and classified.

Treatment advances also have occurred. The acute management of patients with TBI has benefited from advances in neurosurgical intensive care. Medical management of the complications of TBI also has improved. The physical sequelae of TBI such as paralysis, contractures, and HO have been lessened by the same treatments used in the rehabilitation of other physical and neurologic disabilities. Yet, the neurobehavioral deficits of many brain-injured patients represent their most significant obstacles to community reintegration. It is in these cognitive and behavioral realms that our ability to improve function is least clearly defined.

Much research is in progress to refine our classification of these deficits, to clarify the extent to which they are remediable, and to identify the most effective remediation strategies. Because each brain-injured patient's pattern of deficits is unique, it will always remain a challenge to apply the knowledge gathered from group studies to the management of the individual patient. For this reason, a thoughtful interdisciplinary treatment-planning process that considers the complex interactions of the many physical, cognitive, and behavioral deficits is essential.

# Multiple Sclerosis

Multiple sclerosis (MS) is a complex, multifactorial disease that requires the expertise of neurologists, physiatrists, occupational therapists, and physical therapists, as well as countless other participants in the patient's care. Rehabilitation physicians have an integral role during the disease course including the assessment and management of paresis, spasticity, gait, activities of daily living, bowel and bladder function, wellness issues, and pain. Since MS is a long-term and often progressive disorder, the focus is not only on improving function where necessary but also on maintaining function where possible. A firm understanding of the underlying pathophysiology of MS as well as the role and rationale of treatment is the key to the rehabilitative treatment of MS.

MS is the most common cause of nontraumatic disability affecting young adults in the Northern Hemisphere (1). Onset is usually in the 20s to 40s, a time when they are in the core of their working and childbearing years (2). The disease varies from patient to patient and the care needs change from year to year. Thus, it is crucial to have a team approach to maintain and improve function. There are presently six food and drug administration (FDA) approved medications that alter the disease course of MS, and there are more in the pipeline; however, none provides a cure or an alternative to rehabilitative approaches to MS care.

## DEMOGRAPHICS AND EPIDEMIOLOGY

MS is a common disorder in North America. Prevalence varies in the United States and Canada and ranges from approximately 40 to 220 per 100,000 population (3). With some exceptions, the prevalence of MS increases further north and south of the equator one lives (4). Various theories have been proposed to explain this distribution, as well as the notable exceptions to this geographic observation in some populations (Inuit, Laplanders, etc.) (5). Theories include vitamin D deficiency due to reduced sunlight, dairy products, genetic populations, and exposures to a variety of environmental factors (6). MS is preponderantly a disease of persons of Northern European ancestry (7). Infections have been linked to MS, but no one infection has emerged as a specific cause or precipitant of disease activity (8). In pediatric MS, late infection with mononucleosis has been associated with MS (9). Exacerbations of MS are more common after various infections, but the type of infection appears to be immaterial (10).

## ETIOLOGY

MS is considered to be an “autoimmune” diseases (11). Like all autoimmune disorders, it is more common in women (12), occurring about twice as often in women as in men (13). MS also appears to involve genetic factors with HLA-DR2 in DR-positive families—having a greater chance of developing the disease (14). The risk of concordant MS is 30% with monozygotic twins, 5% with dizygotic twins, and between 2% and 4% for first-degree family members of people with MS (15). Multiple genetic linkage studies have confirmed a linkage with the major histocompatibility region, as well as less well defined linkages to other zones that code for interleukins (16). MS is not increased in children adopted into families with MS (17), which indicates that family aggregation of MS is due to genetic factors rather than environmental (18). The specific cause of MS remains unknown.

## PATHOLOGY, PATHOGENESIS, AND PATHOPHYSIOLOGY

The hallmark of MS pathology is the presence of multifocal plaques (lesions) of demyelination in the cerebral hemispheres, optic nerves, brain stem, and spinal cord (19). The early plaque has a demarcated area of demyelination with incomplete axonal injury, inflammatory infiltrates composed of lymphocytes and macrophages, and evidence of astrocytic proliferation and gliosis (20). Ultrastructural analysis of axons has shown an early reduction in axonal fibers and axonal transections in new demyelinating regions (21).

In acute active lesions, gadolinium leaks into tissue parenchyma due to blood-brain barrier (BBB) interruption that accompanies the inflammatory response (22). Perivenular lymphocytic infiltrates are evident in areas of demyelination (23). Macrophages are the most prominent inflammatory cells in the lesion and many are filled with myelin debris (24). Proinflammatory CD4+ T cells appear to be critical components in the demyelinating process (25). B cells from peripheral blood are recruited to the active plaque and differentiate into plasma cells that synthesize and release immunoglobulin (26). Plasma cells are more commonly encountered in chronic lesions (27).

With progression of the pathological process, chronic inactive lesions are less inflammatory and become hypocellular,

with relatively quiescent oligodendrocyte precursor cells (28). Degeneration occurs, as oligodendrocytes are destroyed and astrocytes proliferate. As demyelination occurs, there can also be some degree of remyelination in the lesion (29). However, as the disease progresses, demyelination at the plaque margin takes place in the newly remyelinated areas and leads to expansion of the lesion. This eventually results in permanent scarring.

## PATHOPHYSIOLOGY OF MS

The clinical symptoms of MS are often due to loss of axonal conduction. Demyelination of segments of conducting axons causes conduction block which varies depending on the extent of demyelination and whether compensatory mechanisms have intervened. Conduction block in experimental demyelination occurs at sites of demyelination and does not occur in otherwise unaffected segments (30). The block appears to be most severe in the first few days after experimental demyelination (31). Acutely demyelinated axolemma has a relatively low sodium channel density which may be insufficient for the action potential to be propagated effectively (32).

Another factor influencing conduction is inflammation (33). Cytokines have been shown to play a role in conduction block, particularly proinflammatory cytokines such as tumor necrosis factor- $\alpha$  and interferon (IFN)- $\gamma$  (34). Both of these cytokines induce nitric oxide formation (35). Nitric oxide production is increased in MS (36) and has been shown to cause a dose-dependent conduction block (37).

Safety factor is a measure of the excess current allowing conduction divided by the minimum current necessary to depolarize an axon (38). In normal myelinated axons, this is usually a factor of three to five times. In demyelinated axons this is reduced, often measured at just above 1. Small changes in environmental factors can thus cause axonal block in such fibers (reduced safety factor). This may be the basis for worsening MS symptoms with fever and with exercise, both of which may reduce safety factor to the point where conduction block occurs.

Restoration of conduction occurs in demyelinated axons after a few days or weeks. This is likely related to the appearance of sodium channels along the demyelinated portion of the axon to allow microsaltatory conduction along these demyelinated segments (39). Remyelination occurs with improved conduction in previously demyelinated segments (40). In addition, the resolution of inflammation may also improve conduction block possibly due to normalization of nitric oxide levels (37).

Patients frequently note that with repeated activity they develop weakness, especially with walking. In experimental demyelination, a train of stimuli over time will elicit intermittent conduction block (30). This correlates with hyperpolarization of the membrane (41).

## Restoration, Remyelination, and Neuroprotection

Recovery of function (remission) may be due to resolution of inflammation or the pressure of edema, removal of humoral factors, reattachment of paranodal myelin, or rerouting of nerve transmission through alternative pathways (brain plasticity) (42). Remyelination may also be a key component in the restoration phase, which usually requires days to weeks (43). Early studies of spinal cord MS lesions suggested that regeneration of central myelin is accompanied by Schwann cell invasion of the central nervous system (CNS) and the presence of peripheral myelin within the demyelinated region (29).

A classic neuropathological finding with remyelination is “shadow plaques.” These represent partial reduction of myelin staining as remyelinated axons have thinner myelin sheaths. Such remyelination may be extensive in some patients (44). Remyelination may be seen on magnetic resonance imaging (MRI) as intermediate lesions on T1 images and appear less dark compared to hypodense “black holes” (which represent significant axon damage).

## TYPES OF MS

An international panel was convened in the late 1990s to develop a common classification of subtypes of MS (45) (Fig. 25-1). This classification is useful as a way to group patients, though separations between subtypes may be more artificial than real.

**FIGURE 25-1.** Multiple sclerosis classification.

### Relapsing-Relapsing MS

Relapsing-relapsing patients have discrete attacks of new or worsened neurological symptoms that emerge over a few days and may resolve over a 4- to 8-week period with or without corticosteroid treatment. These patients often return to their preattack baseline but may have residual disability. Relapsing-relapsing multiple sclerosis (RRMS) is the most common form of MS (46). RRMS frequently begins with optic neuritis (ON)—transient unilateral visual impairment lasting days to weeks, which may be associated with retrobulbar pain (47). Others with RRMS may initially experience tingling or weakness of a limb; paresthesias are the most common initial symptom of MS (48). In general, patients with sensory symptoms, and patients whose symptoms fully remit after early exacerbations, demonstrate better long-term prognosis (48). FDA and internationally approved medications are available for patients with RRMS (49–53). These medications in general reduce new exacerbation frequency, reduce measures of MRI activity, and may slow progression of disability. Note that patients who have exacerbations and are left with residual disabilities and those with complete resolution are both still considered RRMS (Fig. 25-1). Nevertheless, from a functional perspective these two patient groups are dramatically different.

### Secondary Progressive MS

These are patients who initially have RRMS but after some years of disease have gradual worsening in between discrete attacks. They may have continued attacks or stop having attacks. They also tend to have fewer attacks and less MRI gadolinium enhancement than during the relapsing-relapsing phase. A significant proportion of RRMS patients convert to secondary progressive multiple sclerosis (SPMS) at some time in their disease course. IFN- $\beta$ 1b and mitoxantrone slow the progression of SPMS if given in the early part of this stage, particularly when there are continued relapses (53,54). However, in older patients who do not have continued relapse activity, the beneficial effect of these medications is less pronounced (55). Patient with accrued deficits such as gait disorder and spasticity may benefit from rehabilitative approaches.

### Primary Progressive MS

Primary progressive multiple sclerosis (PPMS) patients are often older at onset and have a progressive course without attacks. They tend to have fewer MRI lesions than RRMS or SPMS patients. PPMS occurs in about 10% of patients with MS. PPMS tends to affect both sexes equally, unlike RRMS (56). It usually becomes clinically apparent when patients are in their 50s (57). PPMS more often starts with motor symptoms, often an asymmetric paraparesis, and tends to progress more rapidly, validating observations that patients starting with motor symptoms fare less well (vs. sensory symptoms), regardless of disease type (57).

There are no FDA-approved immunomodulating agents for PPMS. Although some have been tried, none has shown sufficient benefit for regulatory approval. Some randomized,

blinded trial efficacy has been reported for methotrexate, but the effect was limited to upper limb function as measured by timed Nine-Hole Peg Testing (58). Pulse methylprednisolone has also been reported in some studies to be useful in this cohort of patients (59).

### Progressive-Relapsing MS

Progressive-relapsing MS is a form of MS where the patient experiences progressive disease at the beginning but begins to have attacks later in their course. Probably no more than 5% of MS patients have this form. Effective medical treatment is unclear for this subgroup.

### Fulminant MS

These are patients with rapid severe progression with relapses over a period of months. This type of MS affects a small percentage of patients.

## OTHER ASSOCIATED DEMYELINATING DISORDERS

### Optic Neuritis

Many patients with MS will present with ON, a sudden unilateral loss of vision, which can vary from a slight central scotoma to complete loss of light perception (47). In one long-term study of ON, 57% eventually developed MS (60). Both ON and ON/MS patients respond favorably to intravenous (IV) methylprednisolone (47). A recent Cochrane analysis of corticosteroid use for ON concluded that there is no evidence of a long-term benefit of high- or low-dose steroids; the improvement seen with high-dose corticosteroids in the ON trials appears to be limited to short-term outcomes (61). Data on patients with clinical isolated syndromes (CIS) such as isolated ON have shown that patients with multiple brain lesions on MRI are at higher risk of progressing to clinical MS within 1 to 2 years after presentation (62). Obtaining a brain MRI in patients with ON or other CIS is therefore an effective risk stratification methodology and potentially guides later therapy.

### Transverse Myelitis

Transverse myelitis (TM) is an inflammatory disorder of the spinal cord (63). It may present after an infection in about half of cases. Most patients have rapid progression to a relatively complete spinal cord syndrome with paralysis, sensory level, and bowel and bladder involvement. Cerebrospinal fluid (CSF) may show a pleocytosis but usually does not show oligoclonal banding (64). Recovery is variable and often incomplete. There are no randomized trials of therapy for classic TM; therapies tried include IV solumedrol, IV immunoglobulins (IVIG), and plasmapheresis (65). A subset of patients, usually with incomplete TM, will develop MS (66). In addition, a subset of TM patients have a positive neuromyelitis optica-IgG (NMO-IgG), which is a subform of Devic's disease (see below). TM patients who eventually develop MS typically present with asymmetric

and incomplete motor or sensory symptoms, whereas those with pure TM not converting to MS generally have symmetric findings and more profound disability (67). Key rehabilitation issues in TM include mobility, spasticity, bowel and bladder management, and avoiding decubitus ulceration and deep venous thrombosis during the acute illness.

### Devic's Disease (Neuromyelitis Optica)

The traditional concept of Devic's disease consists of the subacute combination of relatively severe ON and TM with sparing of the brain (68). With new research, the classification of neuromyelitis optica has undergone significant revision and likely will continue to evolve (69). In general, patients have a combination of ON and TM, both of which can be severe, with initial relative sparing of brain involvement. The spinal lesions tend to be longer (three or more cord segments) than typical MS lesions in the cord (usually one segment only) (69,70). CSF may show a striking pleocytosis or a neutrophilic predominance which would be unusual for MS (71). A recently developed antibody, the NMO-IgG antibody, is positive in 70% of clinically defined neuromyelitis optica and is rarely positive in MS.

## DIAGNOSIS OF MS

The most common presenting course for MS is relapsing symptoms affecting different neurological structures occurring over time ("lesions distributed in time and space"). Common symptoms include fatigue, ataxia, weakness, numbness and tingling, bladder dysfunction, spasticity, cognitive problems, depression, ON, and pain. Notwithstanding multiple revisions over time, the diagnosis of MS still requires the presence of signs and symptoms separated in space and time, or the presence of progressive symptoms with appropriate paraclinical evidence of demyelination (72–75).

### Diagnostic Criteria

Over the years, several sets of diagnostic criteria have been developed. In the 1960s, Schumacher et al. based the diagnosis of MS entirely on clinical findings (72). In the early 1980s, these were modified by Poser et al. to allow laboratory tests to substitute for some clinical criteria (73). Much more recently, as laboratory testing—especially MRI—has improved, laboratory results have been allowed to substitute for even more clinical findings (74,75). Specific MRI criteria to support the diagnosis of MS have been elucidated (76).

In general, the diagnosis of MS continues to be a clinical one with supporting evidence from MRI, CSF, and evoked potentials as needed (75). MRI assists in the diagnosis when it shows characteristic white matter lesions. Lesions in the periventricular, juxtacortical, subcortical, infratentorial, and spinal cord regions are all helpful. The MRI can be used to demonstrate dissemination in space, replacing examination findings in two areas. Repeated MRIs over time showing new lesion formation can also be substituted for further attacks in making a diagnosis. CSF and MRI findings are helpful in

PPMS, particularly in ruling out other causes of a progressive myelopathy such as spinal cord tumor (75). The McDonald criteria allow for consistent diagnostic criteria to be applied and are helpful in epidemiological studies as well as patient recruitment into clinical trials (75).

### Magnetic Resonance Imaging

MRI has become the most important paraclinical tool in the diagnosis and monitoring of MS and related diseases (77). A variety of MRI measures have been used to analyze MS in terms of diagnosis, progression, the acute lesion, subtypes of MS, and monitoring treatment trials (78).

MRI has also been crucial in modifying our concepts of disease pathogenesis and course in MS. In the 1980s, sequential MRI trials showed that new lesion formation occurs five to ten times as often as there were new clinical events, altering the understanding of disease activity during clinically quiescent times (79–81). In addition, MRI has supported the notion of early axonal injury with MS lesions which pathological studies have introduced. Longitudinal MRI measures of atrophy have shown slow but definite atrophy with time in patients with otherwise relapsing MS (82,83). Finally, MRI imaging particularly with FLAIR (Fluid Attenuated Inversion Recovery) has shown that cortical lesions are common in MS, a fact that went unrecognized prior to these imaging techniques (84,85).

MRI has also shown us that there is a limited correlation between the extent of measurable brain disease and measurable disability. Some patients with limited MRI change have significant deficits, and some with extensive white matter and gray matter changes have limited clinical deficits. The explanation for this is unclear but may involve disease in areas not measurably affecting function; compensatory changes that mask functional deficits; spinal cord involvement not imaged on brain MRI causing deficits; and changes that do not cause noticeable neural transmission deficits.

Conventional MRI imaging of MS lesions identifies MS lesions as often paraventricular, oval-shaped lesions, sometimes oriented tangentially to the ventricular surface. Lesions of the corpus callosum are common and extend in a fingerlike pattern, known as "Dawson's fingers" (78). With disease progression, lesions may coalesce. With more chronic and severe disease, brain atrophy becomes apparent. T1 lesions (black holes) are correlated with axonal loss in the affected areas (86).

For several weeks after the occurrence of the breakdown in the BBB, affected brain will be permeable to gadolinium. Consequently, MRIs taken shortly after the IV injection of gadolinium will show "enhancement" or opaque regions on T1-weighted images. A characteristic enhancement pattern for MS is the "open ring sign," where gadolinium enhances in an incomplete peripheral pattern, often pointing away from the lateral ventricles (87).

Other techniques that at present have a primarily research application include brain parenchymal fraction (83), magnetization transfer ratio (88), diffusion tensor imaging (89), and MR spectroscopy (90). These techniques may be most helpful in documenting axonal tract fibers loss and in predicting disability.

## Evoked Potentials

The original work in evoked potentials came from Dawson's lab in the 1940s (91). Dawson and his colleagues showed that one could record neurological activity from the CNS with peripheral stimulation of a sensory pathway using summation of multiple stimulations by averaging. They and others demonstrated slowing of central conduction in MS patients. This was consistent with the concept of a demyelinating disorder as opposed to one with primarily axonal injury. Slowing in the visual evoked potential is the most classic example, but similar slowing can be seen with somatosensory evoked potentials and brainstem auditory evoked potentials (92). American Academy of Neurology guidelines suggested that visual evoked potentials are probably useful to identify patients at increased risk for developing clinically definite MS; somatosensory evoked potentials are possibly useful to identify patients at increased risk for developing clinically definite MS; and there is insufficient evidence to recommend brainstem evoked potentials as a useful test to identify patient at increased risk for developing clinical definite MS (93). There is no data to support repeated evoked potential testing for monitoring of ongoing disease.

## Ocular Coherence Tomography

Ocular coherence tomography is a new technique which allows imaging of the retinal nerve fiber layer (RNFL) thickness (94). It is a sensitive, safe, and reproducible measure that allows analysis of features such as nerve fiber loss, ganglion cell loss, and macular edema. It is being used as an independent measure in clinical trials of medications in MS, and may be a robust marker of fiber loss indicating disease progression (95,96). Its role in clinical decision making is still being evaluated (95).

## Lumbar Puncture

Lumbar puncture and CSF analysis are less often performed today, as improvements in imaging have generally replaced this invasive procedure. However, when done, identification of oligoclonal bands and increased IgG synthesis are associated with a positive diagnosis of MS (97). These findings indicate activity of the immune system in and around the CNS compartment, and as such are not specific for MS. Other diseases such as lupus, Lyme disease, and neurosarcoidosis also may show oligoclonal banding. Studies of the diagnostic accuracy of MRI, evoked potentials, and CSF have shown that if two of three of these tests are positive, the third does not add significantly to the diagnosis (98). Neurologists are reducing the frequency of CSF tests in patients with otherwise typical MS and in whom MRI and evoked potentials are characteristic. CSF studies are most useful in atypical presentations, where the MRI is non-specific, and where other diagnoses are being considered.

## Electrodiagnostic Testing

In general there is no role for electromyography and nerve conduction testing in MS. The peripheral nervous system is usually spared in MS. There are some studies indicating involvement of the proximal aspect of the peripheral nervous system in patients with severe MS, sometimes affecting phrenic

nerve function (99). There are rare patients with central and peripheral demyelination in which electromyography and nerve conduction studies would be useful (100).

## MEDICAL MANAGEMENT

### Corticosteroids

Corticosteroids and adrenocorticotropic hormone (ACTH) have been used in MS therapy for years, well before randomized controlled trials were undertaken in MS therapy. An early randomized trial of ACTH versus placebo for exacerbations of MS showed improvements in disability scores at 4 weeks in patients treated with ACTH compared with patients treated with placebo (101). Over the past 20 years, various studies have shown a similar short-term effect of steroid therapy during exacerbations. Three major randomized equivalence studies showed that IV methylprednisolone was similar to ACTH in terms of efficacy with a more convenient dosing schedule (102–104). Questions about the efficacy of IV methylprednisolone lead to three randomized trials versus placebo that reconfirmed the significant short-term benefit of various IV methylprednisolone regimens versus placebo on neurological function (105,106). A systematic review found a sufficient body of evidence to support the use of IV methylprednisolone in acute exacerbations of MS (107). The usual place for IV steroids is for acute exacerbations that cause functional deficits. The use of steroids has to be balanced against the considerable long-term risks which include occasional anaphylaxis against IV methylprednisolone, osteoporosis, cataracts, aseptic necrosis of the hips or shoulders, diabetes mellitus, etc.

Pulsed IV methylprednisolone given several times a year was shown to slow the development of T1 black holes, delay brain atrophy, and slow progression (108). In a trial of pulsed methylprednisolone for SPMS, patients on treatment were significantly less likely to be a treatment failure (59).

### Interferons

Three IFN- $\beta$  agents are FDA approved for MS. They have similar efficacy in reducing relapse frequency and new MRI activity and have similar side effect profiles.

IFN- $\beta$ 1b (Betaseron) was approved by the FDA for use in RRMS and became available in limited quantities in the United States in late 1993 (49). IFN- $\beta$ 1b was tested in patients with up to a moderate degree of disease severity. A three-armed phase III trial clearly demonstrated a dose-effect curve. (Comparison groups placebo, 1.6 million international units, 8 million international units s.c., alternate day dosing.) In the high-dose group, a 34% reduction in exacerbations and an 83% reduction in active MRI lesions were noted. Side effects of IFN- $\beta$ 1b include injection site reactions, elevation of liver function tests, and rare incidences of autoimmune hepatitis, glomerulonephritis, and immune thyroiditis. There may be an increase in depressive symptoms in patients on IFN therapy. Common side effects include flulike symptoms the night after the injection, which can usually be reduced by anti-inflammatory medications or

acetaminophen. Up to 35% of patients may develop neutralizing antibodies to IFN- $\beta$ 1b which seem to inhibit the efficacy of this medication. In patients with more severe functional symptoms spasticity may increase in IFN therapy.

In 1996, IFN- $\beta$ 1a (Avonex) became FDA-approved for RRMS, based upon a phase III trial demonstrating 18% reduction in exacerbations and a 33% reduction in MRI activity (50). In this study, there was a 37% lower risk of sustained progression of disability as measured by the Expanded Disability Status Scale (EDSS). Side effects include flulike symptoms after the injection, and a lower rate of side effects similar to IFN- $\beta$ 1b. Five to ten percent of patients may develop neutralizing antibodies to IFN- $\beta$ 1a (50).

A third IFN- $\beta$  is approved for the US market is IFN- $\beta$ 1a, s.c., three times a week (Rebif) (51). This agent demonstrated efficacy similar to IFN- $\beta$ 1b.

### Glatiramer Acetate

Glatiramer acetate (GA) (Copaxone) is a mixture of synthetic polypeptides consisting of four amino acids in a specific molar combination. The proposed mechanism is binding to class II major histocompatibility complex with consequent inhibition of myelin-reactive T cells. GA was tested in RRMS patients with an EDSS of up to 5.0 and demonstrated a 29% reduction in exacerbations (52). A subsequent study has shown GA to reduce active lesions on MRI by 35% (109). Side effects include skin injection site reactions, rare arthritic symptoms, and an idiosyncratic reaction in 1/3,000 injections with chest tightness and shortness of breath lasting a few minutes.

### Natalizumab (Tysabri)

Natalizumab contains humanized neutralizing IgG4- $\kappa$  monoclonal antibodies against leukocyte  $\alpha$ 4 integrins. By blocking  $\alpha$ 4 integrins, natalizumab reduces the movement of mononuclear leukocytes into the CNS and small intestine. This medication is given as a monthly IV injection. One pivotal trial of natalizumab showed a reduction in sustained disability from 29% to 17% at 2 years, as well as a reduction in relapse frequency by approximately 70% and reduction in MRI new gadolinium enhancing lesions at year 2 by 92% (110). Two MS patients who were also on IFN therapy developed progressive multifocal leukoencephalopathy (PML) (111). These cases led to the initial withdrawal of natalizumab from market in 2004. Subsequently, it was reapproved with a specific monitoring program and consenting procedure for relapsing forms of MS, in particular for patients who have failed other standard agents (112). The risk of PML and other opportunistic infections in patients on natalizumab monotherapy is still unclear.

### Mitoxantrone (Novantrone)

Mitoxantrone is an anthracenedione, a chemotherapy agent with potent effects on cellular and humoral immune mechanisms. It is the only FDA-approved chemotherapeutic agent for MS. In a clinical trial for secondary progressive patients with continued attacks, it significantly reduced disability progression, reduced attack rates, and reduced MRI measures (53). A dose-dependent cardiotoxicity limits use of the medication to about

2 years of total dose. In addition, there have been case reports of leukemia due to mitoxantrone in patients with MS (113). Other adverse side effects include bone marrow suppression, amenorrhea, and infertility. This drug is usually prescribed by MS experts or by oncologists experienced in handling this drug.

### Other Agents in Trials

Presently, there are about 300 trials listed for MS with clinicaltrials.gov, a National Institute of Health Registry of clinical trials. These include combinations of presently available agents with other medications, medications thought to have neuroprotective effects, medications for symptom management in MS, chemotherapeutic agents, and a variety of novel agents that in general affect immune regulation. Agents with some proven efficacy in MS that are not FDA approved for MS include methotrexate, azathioprine, cyclophosphamide, rituximab, and IVIG. These agents have a moderate toxicity profile, and the data supporting their use are less robust due to smaller trials, less effective blinding, and other confounding factors. A small trial in active severe demyelinating disorders indicated that plasmapheresis was effective in patients who had failed IV steroid therapy and were less than 3 months from the onset of their symptom complex (114). Some studies are beginning to look at specific genetic markers as a potential measure of therapeutic responsiveness. MS is a very active area of research and therapeutics are expected to continue to change dramatically in the next few years.

## REHABILITATION

It is generally agreed that rehabilitation is an important component of the management of patients with MS. A recent expert opinion paper published by the National MS Society summarized general recommendations for the use of rehabilitation in MS (115). In practice, rehabilitation professionals are faced with serious challenges when attempting to apply rehabilitative interventions to MS patients.

MS is overall a progressive neurologic disease, which does not follow the traditional model of rehabilitation (acute medical event or injury, functional recovery, and readaptation into the environment), with the notable exception of severe disease exacerbations. The best timing for rehabilitation interventions is not well defined. Too often, patients are referred late, when impairments are fixed and opportunities for functional improvement are limited. Payors usually allow a small number of therapy sessions every year when many MS patients have ongoing needs, and demonstration of progress is required to continue therapy, when preventing functional loss is essential in reducing the individual and societal costs of the disease.

Variability and unpredictability make it difficult to apply standard rehabilitation protocols in MS. Clinical presentations are highly heterogeneous, and intricate impairments are an obstacle to functional compensation. Symptoms and functional performance vary over time, even within the course of a day, but not always with a consistent pattern, giving a feeling of “trying to hit a moving target.” Furthermore, transient

worsening of MS symptoms is frequently encountered with exertion, and compromises patients' adherence to therapy sessions and home exercise programs.

### Evidence Supporting the Use of Rehabilitation in MS

In the expert opinion paper cited above, the National MS Society acknowledged a need for stronger evidence to support treatment recommendations. There is, however, a growing body of data regarding MS and rehabilitation.

#### Neuroplasticity

CNS plasticity has been more widely assessed after stroke and brain injury, and specific interventions, such as constraint-induced movement therapy or partial body weight supported treadmill training, have yielded interesting results. A recent review of the literature on fMRI in MS highlights evidence supporting the existence of cortical reorganization in MS patients (particularly in the visual, cognitive, and motor systems) (116). Morgen et al. reported a correlation between functional improvements after physical therapy, and changes in functional sensorimotor signaling patterns in the brain (117).

#### Aerobic Exercise

Deconditioning has been identified as a significant contributing factor to fatigue in MS (118). The benefits of exercise on fitness, activity level, subjective fatigue, and perceived health status, have been demonstrated in randomized controlled studies (119,120). In practice, it is often difficult for patients to initiate a sustainable exercise routine without the guidance of a rehabilitation professional, to find the appropriate type, intensity, and duration of exercises, and to encourage the patient through a usually difficult initial period for the first few weeks. Traditional outpatient therapy is appropriate. Short

intensive programs, such as the Jimmy Heuga Center CAN DO wellness program, are also an option.

#### Recovery after Exacerbations

Even when treated with high-dose corticosteroids, MS exacerbations often leave patients with residual impairments (121). In fact, exacerbations have been identified as the main cause of accrual of disability in relapsing forms of the disease (122). Inpatient or outpatient multidisciplinary rehabilitation may also enhance functional recovery (123,124). It remains to be determined if neuroplasticity plays a role, or if most of the benefits of rehabilitation in this context stem from optimized adaptation and compensation strategies. Less intensive outpatient rehabilitation may not be as effective (125).

#### Rehabilitation of Chronic Disability

Several controlled trials showed objective and/or subjective benefits from multidisciplinary inpatient (126,127) or outpatient (128) rehabilitation, mostly in patients with a progressive disease course. If we assume that rehabilitation does not affect the disease process, these results suggest that some of the disability progression is not directly related to disease activity.

#### Disease-Specific Outcome Measures for MS Rehabilitation

Generic outcome measures used in rehabilitation, such as the Barthel Index and the Functional Independence Measure (FIM), can be applied to MS patients (126,129). However, these measures are often not sufficient, because they do not cover specific aspects of the disease (e.g., fatigue, visual disturbance), lack sensitivity to small but significant changes over time, or exhibit a ceiling effect (particularly with regard to cognitive disability). Many disease-specific instruments, although often not developed and validated in a rehabilitation setting, can be useful in clinical practice and in research studies (Table 25-1).

**TABLE 25.1** Disease-Specific Outcome Measures for MS Rehabilitation

Scale Name	Acronym	Dimension Assessed	Mode of Administration
Expanded Disability Status Scale (212, 213)	EDSS	Impairments/ambulation	Standardized neurological examination/observation of walking performance
Incapacity Status Scale (212, 213)	ISS	Disability	Observation of performance/interview of patient and/or caregiver
Environmental Status Scale (212, 213)	ESS	Handicap	Interview of patient and/or caregiver
Multiple Sclerosis Functional Composite (214)	MSFC	Impairment/disability	Three simple tests (Timed 25-Foot Walk, Nine-Hole Peg Test, Paced Auditory Serial Addition Test—3 min)
Neuroperformance Testing (215)	NPT	Impairment/disability	Quantitative neurologic tests
Scripps Neurological Rating Scale (216)	SNRS	Impairment/disability	Standardized neurologic examination
Ambulation Index (217)	AI	Walking performance	Observation of gait performance on 25 ft
Multiple Sclerosis Impact Scale-29 items (218)	MSIS-29		Patient survey
Multiple Sclerosis Walking Scale-12 items (219)	MSWS	Patient-reported walking performance	Patient survey
Multiple Sclerosis Quality of Life Inventory (221)	MSQLI	Patient-reported health status and symptom severity	Patient survey
Multiple Sclerosis Quality of Life-54 (220)	MSQOL-54	Patient-reported health status and symptom severity	Patient survey

## SYMPTOM MANAGEMENT

MS is a condition that leads to multiple symptoms affecting function (fatigue, bladder dysfunction, spasticity) and well-being (pain, paresthesias). Close attention to symptom management may be useful in allowing patients to function at their optimal level, while reducing the amount of discomfort.

### Heat Intolerance

Worsening or recurrence of preexisting neurologic symptoms with heat (from a hot environment or from elevated body temperature) is a very common phenomenon, and was even used to support the diagnosis of MS in the past (130). Reduced safety factor for neurological transmission due to demyelinated or partially demyelinated axons is a likely mechanism (see Pathophysiology). Heat intolerance can limit a patient's potential to participate in rehabilitation and exercise. Adjusting air or water temperature, using fans, cooling vests, or heat extraction units, and the medical recommendation of air-conditioning units in the home, are all practical and valid management tools.

### Transient Neurological Events

A common but underrecognized problem in MS is transient neurological events (TNEs). These were reported in one series in as many as 20% of patients (131). These consist of stereotyped, brief (seconds), frequent (up to 100s of times a day) events with neurological symptomatology. Dystonic posturing of a limb, weakness, visual disturbances, dysarthria, abnormal sensations, and muscle spasm can all be seen, often in combination. These events are often not reported by patients without direct questioning, as they do not conform to the general pattern for an attack of MS. They are likely due to ephaptic transmission between demyelinated fibers and are not a cortically based seizure phenomenon. They usually occur over a period of weeks and resolve, and may represent a new demyelinating event. Often an explanation is helpful to the patient to understand what is transpiring. If needed, treatment with low-dose antiepileptic medication can be effective (carbamazepine, topiramate, etc.).

### Spasticity

Spasticity (defined as a velocity-dependent increase in stretch reflexes (132)) and decreased motor performance (weakness, loss of dexterity), both of which are components of the upper motor neuron syndrome, frequently coexist in MS patients, and represent a major source of disability. Treatment planning, particularly when functional improvement is sought, must take both into account, since interventions may have a different effect on each of them.

In a large survey of over 20,000 participants in the North American Consortium of MS (NARCOMS) Patient Registry, 84% of the subjects noted spasticity-related symptoms, and approximately one-third reported that spasticity was severe enough to affect their daily activities (133). Even though outcome measures and interventions used in other CNS

conditions can all be applied to MS patients, evaluating and treating spasticity in MS can be challenging. Due to the presence of associated impairments, and due to the heterogeneity of clinical presentations, it is difficult to evaluate the impact of spasticity (and its treatments) on functional performance and subjective well-being. Furthermore, side effects from symptomatic therapies (particularly sedation and weakness) can make it difficult to reach effective doses. Clinical practice guidelines for the management of spasticity in MS have been developed based on a review of the literature and expert consensus (134).

Spasticity in MS is usually considered of spinal origin, although features of cerebral origin spasticity are also encountered. Patient complaints can be confusing; for example, a patient reporting increasing difficulty bending the legs and sensation of tightness with walking may be experiencing fatigability and abnormal sensations rather than spasticity. Examination will seek static (resistance to passive movement, decreased range of motion) and dynamic (synergy patterns, co-contraction of agonist and antagonist muscles, posture-dependent hypertonia, clonus, spasms) features suggestive of spasticity. It is essential to evaluate the patients at rest and during a functional activity such as walking. Even if the elements above allow for "diagnosis" of spasticity and its severity, they are not sufficient for treatment planning. The impact of spasticity-related phenomena on the patient and caregivers, the patient's personal characteristics and preferences, and disease-related constraints will all influence treatment decisions. Therefore, outcome measures should include not only symptom severity (stiffness, pain, spasms) and impairment ratings (Ashworth or Tardieu scale, range of motion, muscle strength) but also measures of passive and active function and satisfaction with treatment.

Overall, there is limited published evidence to support the efficacy of most antispasticity agents in MS, and there are methodological concerns with most studies (135). Some of the treatments are used off label for this indication. Controlled clinical trials have demonstrated the efficacy of oral baclofen (136), tizanidine (137), gabapentin (138), benzodiazepines (139), and dantrolene sodium (140) in patients with MS. The benefits usually consisted of symptom relief (e.g., stiffness, spasms, spasticity-related pain), decreased resistance to passive movement, and improved range of motion. Objective functional benefits (e.g., on ambulation), however, were either not assessed or not found. Increased weakness, and sometimes functional deterioration, were reported with baclofen and benzodiazepines (139), but these occurred less frequently with tizanidine (137). Sedation is another major side effect of antispasticity medications, and may not allow titration to effective doses. In practice, the "start low, increase slow" rule must be applied, but high doses can be used if tolerated, and medications can be combined when spasticity is severe, or when dosing is limited by side effects. Reports of liver toxicity with some of these agents (particularly dantrolene, tizanidine, baclofen) must be kept in mind, particularly when patients are on potentially hepatotoxic disease-modifying therapies such as

IFN- $\beta$ , azathioprine, cyclophosphamide, and mitoxantrone. More recently, levetiracetam was reported to be helpful with phasic phenomena associated with spasticity (141).

Chemodenervation and chemical neurolysis can be used to treat focal spasticity, or diffuse spasticity with focal problems. Onabotulinum toxin A was recently approved by the FDA for the treatment of upper extremity spasticity in several CNS conditions, including MS. There are only a few published clinical trials of botulinum toxin (BT) in MS (142). The advantages of local injections include a lower occurrence and severity of side effects compared to other treatment, and the ability to specifically target muscles. However, criteria for patient selection and dosing algorithms need to be more carefully studied in the context of MS. A high rate of therapy discontinuation associated with disease worsening has been reported (143).

Among the treatments for spasticity requiring a surgical intervention, intrathecal baclofen (ITB) therapy is by far the most frequently used in MS, and there is a fairly large body of evidence regarding its efficacy, side effects, and complications (144–146). ITB therapy is approved by the FDA for the treatment of severe spasticity of spinal or cerebral origin refractory to oral antispasticity medications, or when oral medications are not tolerated. The intrathecal route of administration allows for effective CSF concentrations with markedly smaller doses and plasma concentrations of baclofen. Therefore, a larger effect is achieved with reduced incidence of CNS sedation compared to the oral route. However, the risk of inducing weakness is higher, and for this reason ITB therapy has been used mostly in nonambulatory patients with severe lower extremity spasms and contractures. The benefits of ITB in this patient group should not be underestimated, and include relief of discomfort and pain related to spasticity, enhanced ease of care, improved posture, and improved ability to transfer (146). Some patients are able to improve from a mostly bedbound state to spending most of the day in a wheelchair. In the NARCOMS survey cited earlier, patients receiving ITB reported lower levels of spasticity and higher satisfaction with treatment, compared to patients treated with oral baclofen (133). Recent reports have shown that ITB can be utilized in ambulatory MS patients without loss of function (147,148). Benefits in this patient group include not only relief of spasticity-related symptoms and objective reduction of hypertonia but also subjective improvement of function and quality of life (149) and objective improvement of specific gait parameters (150). Opiates and clonidine have also been used intrathecally to treat intractable pain and spasticity in MS, alone or more frequently in combination with baclofen (151).

## Weakness

Decreased voluntary motor output in the extremities and trunk can be observed with or without spasticity. Multiple factors account for the observed weakness, including decreased motor control from the CNS; immobility and deconditioning; spasticity; chronic elongation of muscles due to positioning; heat; and fatigue. Increased weakness with effort is thought to be related to nerve conduction blocks in the CNS, but could also be related to muscle fatigue with impaired muscle excitability

and metabolism (152). In addition, other symptoms such as pain may inhibit motor performance.

Fluctuations in motor performance are the hallmark of MS, which complicate testing and treatment planning. The interview is essential in differentiating weakness from subjective fatigue or other causes of altered movement and defining the characteristics of weakness (localization, duration, timing, aggravating factors) and its impact. The Medical Research Council manual muscle testing, or even dynamometry (153), can be used to evaluate the severity of muscle weakness. Functional testing is essential, and in a busy clinical practice, may consist of simple tests such as the Timed 25-Foot Walk or the Nine-Hole Peg Test. In a rehabilitation setting, the patient can be challenged with a variety of tests and exercises and/or prolonged effort. In the ambulatory patient, motor fatigue can be evaluated with tests of walking endurance such as the 6-minute (154) or 2-minute (155) walk tests. Most tests of walking performance are performed on level ground, which does not reflect the diversity of terrains encountered in daily life, even within a patient's home. The Mellen Center Gait Test (MCGT) was recently developed to reproduce the variety of terrains encountered in real-life situations (156).

There are few interventions aimed directly at muscle weakness. Spasticity management, particularly stretching, and functional training are indirectly helpful. Improvement of muscle strength has been reported after aerobic exercise (119) and progressive resistance exercises (157). These exercise programs must be highly customized to the specific limitations of MS patients, particularly in terms of intensity and duration of exercises. Since the increase in body temperature due to physical activity is thought to be at least in part responsible for motor fatigue, pre-exercise cooling may improve performance and increase the benefits of exercise (158). Symptomatic medications for fatigue, such as amantadine and modafinil, may improve motor performance and decrease motor fatigue. Treatments for spasticity could improve muscle strength by reducing the co-contraction of antagonist muscle groups, particularly when administered as local injections. In the context of an exacerbation of MS, high-dose steroids may improve muscle strength as they hasten neurological recovery.

4-Aminopyridine (4-AP) is a potassium channel blocker which facilitates conduction in demyelinated axons. An extended release form of 4-AP was recently approved by the FDA (Ampyra™, dalfampridine) to improve walking in patients with MS, based on significant improvement in walking speed in 2 phase III clinical trials. Beneficial effects on lower extremity muscle strength were also noted (159). The rate of patients responding to the drug in the trials was 35% and 43%. Dalfampridine is administered at the dose of one 10 mg tablet twice daily (approximately 12 hours apart), with or without food. A history of seizure and moderate or severe renal impairment are contra indications to this medication. Side effects occurring at a rate greater than 2% and more frequent with the drug compared to placebo were urinary tract infection, insomnia, dizziness, headache, nausea, asthenia, back pain, balance disorder, multiple sclerosis relapse,

**FIGURE 25-2.** **A:** Sagittal T1-weighted image 0.93 T brain. A 57-year-old female with secondary progressive MS. Note thinning of corpus callosum. **B:** Axial T2 Flair image 1.5 T brain. A 37-year-old male with 2-year history of relapsing MS. Multiple paraventricular oval-shaped lesions. **C:** Sagittal T2 Flair 1.0 T cervical cord. paresthesia, nasopharyngitis, constipation, dyspepsia, and pharyngolaryngeal pain. The risk of seizure (in the absence of history of seizure) is low at the recommended dose. In phase II trials, higher doses of dalfampridine resulted in increased risk of seizure without substantial added clinical benefit.

Assistive devices and orthoses, in addition to their benefits in terms of safety, help compensate for weakness by reducing the energetic demands of activities and by replacing the action of weak muscles. The best illustration is the ankle-foot orthosis (AFO), which improves gait efficiency and safety by compensating for ankle dorsiflexor weakness and often ankle plantar-flexor spasticity. However, the AFO is a passive device and does not compensate for hip flexor weakness, which is a frequent cause of foot clearance deficit in MS. An active orthosis was recently developed under the name of hip flexion assist orthosis (HFAO) in order to address these problems. The HFAO consists of a proximal waist attachment, a medial and a lateral dynamic tension band, and a distal connector that attaches to the shoelaces. All the components are adjustable (Fig. 25-2). An uncontrolled pilot study of the HFAO on 21 ambulatory MS patients showed significant improvement in pain, walking speed, walking endurance, and performance on the MCGT, as well as muscle strength in the “affected” leg (160).

Functional electrical stimulation (FES) is another way to compensate for a lack of strength output in an active manner, by causing the contraction of select muscles to enhance function. In spinal cord injury and stroke, upper and lower extremity FES systems have been more extensively tested and are more commonly used. Several FES devices for foot drop (e.g., Odstock Dropped Foot Stimulator [ODFS], NDI Medical, Cleveland OH [USA]; NESS L300, Bioness Inc., Valencia, CA [USA]; WalkAide, Innovative Neurotronics, Austin TX [USA]) are

currently used in MS patients. These devices produce peroneal nerve stimulation during the swing phase to help with foot clearance, and all but one use a heel switch to time the stimulation accurately. There is preliminary evidence suggesting that functional peroneal nerve stimulation increases walking speed and reduces the effort of walking in MS patients (161). Further studies are needed to refine selection criteria, recommendations for use, and patient/clinician expectations.

## Fatigue

Fatigue is one of the most common symptoms accompanying MS (162). This appears to be most pronounced in the afternoon, and is associated with limited activity in 78% of patients in one survey (131). Fatigue is a subjective symptom defined as “lack of physical and/or mental energy which is perceived by the individual or caregiver as interfering with usual and desired activities” (118). In general, the magnitude of subjective fatigue often does not correlate with an objective observed performance. Fatigue may be a direct effect of immunological activity in the brain, similar to the fatigue associated with viral illness (163). In addition, functional MRI studies have shown that MS patients use more brain areas less efficiently than able-bodied normal controls to achieve the same task (164). This may be the physiological correlate of the complaint of “being unable to multitask,” as well as another cause for MS-related fatigue. Fatigue in MS does not correlate with brain measures of disease burden or atrophy (165). Subjective fatigue usually does not correlate with objective changes in motor or cognitive performance, but does correlate with depression. Fatigue measurement scales (e.g., Fatigue Severity Scale, Modified Fatigue Impact scale) are useful to track outcomes (166).

Clinical practice guidelines for the evaluation and management of fatigue in MS are available (118). A thorough baseline assessment is essential, both to characterize the symptom and to detect treatable causes or contributing factors such as medications, poor sleep, depression, infection, and thyroid dysfunction. Energy conservation strategies constitute the first line of treatment: timing of activities, rest periods and naps, and use of assistive devices to decrease the energy demands of activities. The benefits of exercise were described above; an optimal exercise routine will incorporate stretching, resistance exercise, and cardiovascular training. A recent trial of yoga in MS showed beneficial effects on fatigue over 6 months (167). Cooling techniques address heat sensitivity (168). All of the medications for MS fatigue are used off label. Amantidine, an antiviral agent, showed efficacy in some patients with MS-related fatigue in a small randomized clinical trial (169). Modafinil has been shown to reduce MS-related fatigue in standard doses (100 to 400 mg/day) in a single-blinded trial (170), but these results were not reproduced (171). A variety of stimulant medications have been used empirically but there is little evidence in the literature to support their use. A recent double blind, placebo-controlled trial showed that 650 mg of aspirin twice daily significantly reduced fatigue associated with MS (172).

### Bladder Dysfunction

Bladder dysfunction affects up to 90% of MS patients (173) and correlates with disease severity and disability, but not with disease duration (174). Urinary symptoms affect daily activities, employment, social life, and quality of life in general. Furthermore, urinary tract infections, usually secondary to urinary retention, can cause worsening of MS symptoms and increased disease activity.

Although there are wide variations in the reported prevalence and incidence of urinary symptoms in MS, urgency and frequency are consistently noted as the most frequent, followed by incontinence, hesitancy, and retention (175). While the presence of urinary symptoms is highly correlated with abnormal test results, bladder dysfunction can often be found in the absence of complaints. This is particularly true with urinary retention. Workup for neurogenic bladder dysfunction usually includes urinalysis and urine culture, post-voiding residual (PVR) volume measurement, and urodynamic testing. A renal ultrasound and other upper urinary tract imaging studies may be ordered, particularly in patients with detrusor-sphincter dyssynergia (DSD) or indwelling catheter, but upper urinary tract complications are relatively rare in MS compared to other neurologic conditions (174). Education, with teaching of “bladder hygiene” (e.g., adequate fluid intake, avoiding bladder stimulants), is often helpful in reducing urinary symptoms, particularly those related to detrusor hyperreflexia. Other management options include pelvic exercises, medications, catheters (preferably intermittent catheterization [IC], sometimes indwelling catheter), and less frequently surgical interventions.

Detrusor hyperreflexia, the most common bladder function disorder in MS, is often treated with anticholinergic medications, such as hyoscyamine, oxybutynin (Ditropan), or tolterodine (Detrol). Side effects constitute the main limitation to the use of these medications, and may be less severe with extended-release formulations (176), or with the transdermal formulation of oxybutynin. More recently released anticholinergic medications include trospium chloride (Sanctura), solifenacin succinate (Vesicare), and darifenacin (Enablex). Desmopressin acetate (DDAVP) nasal spray or tablet may be useful in reducing nocturia and enuresis in MS patients (177). BT injections in the detrusor muscle can decrease detrusor hyperactivity for up to 9 months, but may cause temporary retention requiring IC (178). BT injections in the detrusor may be a useful complement to IC when patients experience incontinence between catheterizations. Surgical treatment options are considered when conservative management failed, and include augmentation cystoplasty (in most cases with an abdominal catheterizable stoma) and sacral denervation. Encouraging results have been reported with sacral root stimulation in carefully selected MS patients (Interstim device) (179).

DSD consists of sphincter contraction coinciding with detrusor contraction, leading to incomplete bladder emptying. DSD often occurs in combination with detrusor hyperreflexia; therefore it is strongly recommended to measure the PVR before initiating treatment with anticholinergics in patients who experience urgency and incontinence but do not already perform IC. Alpha-1 selective antagonists (e.g., terazosin) may improve bladder emptying. There are anecdotal reports of the efficacy of BT injections in the sphincter in MS patients with DSD. A randomized placebo-controlled trial failed to show a significant change in PVR after a single injection of BT-A in the sphincter, although voiding volume and detrusor pressures were significantly improved (180). Sphincterotomy or the placement of a urethral stent can be performed, for example when IC is not feasible, but requires adequate detrusor contractility to be fully effective. Another cause of urinary retention is detrusor hypocontractility (sometimes associated with detrusor hyperreflexia), which is more frequent in MS than true detrusor areflexia. IC is the most common treatment for detrusor hypocontractility. Bethanechol (Urecholine) is usually not effective in MS. Surgical interventions for urinary retention include the placement of a suprapubic catheter, which may be easier to manage than an indwelling Foley catheter, and incontinent urinary diversion.

### Bowel Dysfunction

Constipation is the most commonly reported symptom of bowel dysfunction in MS, followed by fecal urgency and incontinence (181). The pathophysiology of neurogenic bowel dysfunction is not well elucidated. There are many factors contributing to bowel dysfunction, including immobility, inadequate diet and fluid intake, and side effects of medications. Patient and caregiver education is key to a successful bowel management program. In addition to remediating the

factors listed above, fiber supplements (e.g., Metamucil), bulk forming agents (e.g., psyllium), and stool softeners (e.g., docusate sodium) are often helpful and may be supplemented with suppositories and enemas. Anticholinergic medications may help with fecal urgency and incontinence.

### Sexual Dysfunction

Sexual dysfunction is frequent in MS patients, who often wish to remain sexually active (182). Sexual dysfunction was found to be correlated with lesion burden in the brain (183). Other consequences of MS, including concomitant neurologic symptoms (fatigue, decreased sensation, spasticity), depression, and marital relationship problems, often contribute to sexual dysfunction. Men usually report erectile dysfunction (ED), decreased libido, delayed ejaculation, and impaired genital sensation. The most common complaints in women include fatigue, anorgasmia, and decreased vaginal sensation. A thorough interview and examination, including the evaluation of perineal sensation, and in women pelvic examination, will guide treatment planning. Complementary testing is not often performed. Education and counseling are useful in both sexes, as a good relationship is key to intimacy. Phosphodiesterase-5 inhibitors (sildenafil [Viagra], vardenafil [Levitra], and tadalafil [Cialis]) are very popular in the treatment of male ED, although these medications do not necessarily resolve all the problems involved in sexual dysfunction. Other, less often used approaches include vibratory stimulation, vacuum pumps, papaverine or prostaglandin E1 injections, and implanted penile prostheses. Pharmacological treatment options for female sexual dysfunction are more limited. The results of a small double-blind trial of sildenafil in women with MS yielded disappointing results, with only a significant improvement of vaginal lubrication (184). The management of other contributing symptoms, vibratory stimulation, and adequate sexual positioning, can be helpful.

### Tremor

Tremor in MS is often associated with ataxia, and may include rest, postural, and action components (“rubral tremor”) (185). The pathophysiology of this very debilitating symptom is not completely elucidated, although the role of the thalamus has been more extensively studied. Tremor severity and the outcome of interventions have often been measured with Fahn’s Tremor Rating Scale. Rehabilitation interventions include the use of assistive devices and technologies, and wrist weights (which can be difficult to use if weakness and fatigability are present) (186). Several medications were reported to be effective on MS tremor, including isoniazid, glutethimide, primidone, levetiracetam, carbamazepine, oral tetrahydrocannabinol, clonazepam, and propranolol, but in practice the results of pharmacological treatments are disappointing in the majority of cases. Thalamotomy, (187) and more recently deep brain stimulation, (188) have been used in MS patients with severe tremor. Positive results were reported in studies of small cohorts of MS patients, but patients were not often followed after 12 months. A rapid decrease in effect leading to the need

for more frequent stimulator adjustments has been reported, as well as upper extremity weakness concomitant to the reduction of tremor.

### Pain

The old saying “MS doesn’t cause pain” is contradicted by clinical experience and numerous publications. Up to 81% of MS patients experience pain at sometime in the course of their disease (189). Pain is often multifactorial and multifaceted in MS. It is sometimes thought to be a direct consequence of the disease process, such as neuropathic pain and pain related to inflammation and upper motor neuron damage. Musculoskeletal pain and headaches are also common.

### Neuropathic Pain

Neuropathic pain is frequently encountered in MS (190). It may present as dysesthesia, allodynia, and/or neuralgia, and is often associated with other sensory disturbances. Partial TM can be associated with a painful band sensation around the trunk, sometimes called the “MS hug.” Chronic dysesthetic pain is often described as burning, but patients are sometimes at a loss when trying to characterize their pain. The pain is thought to originate from lesions in the CNS. Anticonvulsants and antidepressants (tricyclic and more recently selective serotonin reuptake inhibitors (SSRIs)) are commonly used to treat neuropathic pain in MS, despite a lack of solid published evidence to demonstrate their efficacy in this population. The potential side effects of these medications, particularly sedation, should not be overlooked (191). The use of opioids remains controversial (192). A recent randomized clinical trial and open-label extension study have shown that cannabinoids are effective in relieving neuropathic pain in MS (193,194), but their use is limited by side effects and legal considerations. Trigeminal neuralgia is experienced by up to 10% of MS patients in the course of their disease, usually involving the second and third divisions (195). This syndrome is believed to arise from ephaptic transmission of nerve conduction, which occurs with demyelination in the area around the trigeminal nerve entry zone. Carbamazepine and other anticonvulsants are usually effective. When the pain is refractory to oral medications, treatment options include glycerol injections, balloon ablation of the trigeminal nerve, and radiofrequency thermal or surgical rhizotomy.

### Pain Related to Upper Motor Neuron Damage

Spasticity can be associated with pain. Nocturnal painful spasms have been described in MS (196). These are defined as transient painful extensor or flexor spasms of the legs, lasting seconds to minutes, often occurring at night. These may significantly interfere with sleep and increase daytime fatigue. An open-label trial of gabapentin at night showed that 20 of 22 patients experienced reduction in their nocturnal painful spasms with an acceptable side effect profile (196).

### Pain Related to Inflammation

Retro- and periorbital pain, aggravated or triggered by eye movement, often occurs in the context of ON and usually improves

with corticosteroid treatment. Retroorbital pain without visual disturbance is of unclear significance and may respond to steroid or nonsteroidal anti-inflammatory agents.

### Musculoskeletal Pain

Back, neck, upper and lower extremity pain of musculoskeletal origin are commonly encountered in the general population, and as a consequence may occur concomitant to MS, particularly as a result of aging. This issue should not be neglected, because it represents a source of added disability, discomfort, and medical complications. Indeed, MS and its treatments increase the risk of musculoskeletal problems. For example, abnormal posture and body mechanics as a result of weakness, spasticity, and/or loss of coordination, may cause excessive joint stress. Falls related to neurologic impairments can cause fractures and other injuries. Corticosteroid treatments increase the risk of aseptic necrosis of the femoral head, and in combination with immobility are a risk factor for osteoporosis and subsequent complications. Even if the diagnosis of musculoskeletal problems is straightforward, confusion may arise when it is combined with other types of pain, or when several etiologies are possible. For example, radicular pain can arise from demyelination as well as nerve root compression. When in doubt, additional testing and referral to a musculoskeletal specialist are helpful.

### Headache

Although headache is a common complaint among MS patients, its relationship to MS is unclear. In one survey, headaches were no more common in MS patients than in age-matched controls (131). In another, there was a higher prevalence of headaches among MS patients over controls (197). Focal facial pain syndromes (e.g., trigeminal neuralgia) and retroorbital pain, particularly with eye movements, are likely to be MS-specific. Since MS patients often take multiple medications, headache might be related to drug side effects. In general, headache should be treated on its own merits, even if it is in some fashion related pathophysiologically to MS activity.

### Visual Impairment

Visual disturbance occurs in a little over one fourth of all MS patients, and often fluctuates, similar to other MS symptoms, making it more difficult for the patient to adapt. Unfortunately, there is no treatment for the residual visual loss after ON. Even when visual acuity is satisfactory, contrast sensitivity and color perception may be impaired. Night driving may be compromised. Patients should undergo yearly eye examination surveillance for conditions amenable to treatment or correction. The use of steroids may increase the risk of developing cataracts, and uveitis is encountered in 1% of patients with definite MS. Large-print reading materials and computer-based magnification systems may be helpful in patients with severe visual compromise. Patients with photophobia will benefit from the use of sunglasses. Corrective surgery is rarely recommended in MS patients with diplopia. Alternative interventions include the use of an eye patch and

prisms. Oscillopsia sometimes responds to anticonvulsants or baclofen (198).

### Depression

Depression is a common problem in MS. A large population survey of 739 MS patients in King County, Washington, found the point prevalence of significant depressive symptoms to be 41.8% (199). Suicide is an unfortunate but not uncommon phenomenon in the MS population (200). Depression may be increased with IFN therapy for MS, but treatment appears to be effective despite this (201). Depression often contributes to fatigue and perceived cognitive difficulties. Monitoring for the presence of depression as well as a proactive approach to its treatment is crucial. Despite a lack of large placebo-controlled clinical trials in MS, antidepressant medications are widely used. Some antidepressants are considered “energizing” (e.g., paroxetine [Paxil], bupropion [Wellbutrin]) and may be of interest in the presence of severe fatigue. A recent placebo-controlled randomized clinical trial of paroxetine for major depression in MS patients showed no significant effect (202). Behavioral interventions such as counseling are often recommended.

### Cognitive Impairment

Cognitive impairment represents a significant problem in persons with MS. Comprehensive neuropsychological (NP) testing suggests that over 40% of MS patients show cognitive impairment to at least some degree (203). Common complaints include forgetfulness, decreased attention/concentration, difficulty with multitasking, and “cognitive fatigue.” While some patients will exhibit obvious cognitive deficits and may meet the diagnostic criteria for dementia, in many cases the standard interview and testing during a routine visit will not detect significant abnormalities. Comprehensive NP testing typically demonstrates selective deficits in attention, information-processing speed, working memory, verbal and visuospatial memory, and executive functions (204). Disease-specific screening tools and short batteries have been validated (205) and single tests such as the Paced Auditory Serial Addition Test and the Symbol Digit Modalities Test have been suggested as outcome measures in clinical trials (204). Advanced imaging techniques (e.g., functional MRI, diffusion tensor imaging) may provide a better insight into the physiological and anatomical correlates to cognitive impairment than standard MRI.

The management of cognitive impairment often starts with educating (and often reassuring) the patient about their specific deficits and addressing contributing factors, such as depression, fatigue, heat intolerance, or medications. Sleep disorders, particularly obstructive sleep apnea, should not be overlooked. Rehabilitation interventions typically rely on the use of compensatory strategies (e.g., pacing, memory aides) and environmental adaptations, but there is an emerging literature on cognitive training in MS. Acetylcholinesterase inhibitors used to treat Alzheimer’s disease (e.g., donepezil [Aricept], memantine [Namenda]), although not FDA-approved in MS, are used and may be helpful (206).

## Speech and Swallowing Problems

More than one in five MS patients reports problems with speech or communication (207). Dysarthria, decreased voice intensity, cognitive impairments, fatigue, and depression, may all contribute to decreased communication. Dysphagia is also relatively frequent, and may range from intermittent mild problems to chronic aspiration requiring percutaneous endoscopic gastrostomy (PEG) tube placement. Addressing these issues usually requires referral to a speech-language pathologist, and psychologist if indicated (208).

## SOCIAL, VOCATIONAL, AND FINANCIAL MANAGEMENT

Similar to many chronic conditions, MS affects the interaction between the patient and the outside world (209). Caregiver burden is increased by the presence of psychiatric and cognitive impairments (210). Even if rehabilitation professionals are used to help patients and their families deal with the social, vocational, and economic consequences of disabling conditions, some characteristics of MS complicate management: the disease is typically diagnosed in early adulthood, when the patients are still in the process of building their personal and professional life; the evolution of the disease is unpredictable and symptoms fluctuate, making it difficult for the patient to adjust and plan ahead; disease-modifying therapies are expensive, and even with health insurance, an increasing portion of the cost is left to the patient; and functional limitations often result from a combination of impairments and subjective symptoms which may not be fully ascertained by a standard neurologic examination. Even if maintaining employment is desirable for social, psychological, and financial reasons, the worsening of MS symptoms with stress at work, the difficulty of getting reasonable accommodations in the workplace, and the negative impact of fatigue from work on family and leisure activities, may force the patient to stop working and apply for disability benefits (211).

## WELLNESS

Patients with MS will develop the same pathologies that afflict the general population. In addition, MS (and sometimes treatments for MS) may increase the risk for secondary medical problems, which in turn may have an impact on MS symptoms. For example, urinary tract infections due to neurogenic bladder often cause a worsening of MS symptoms; osteoporosis decreases mobility; and steroid use increases the risk of fractures. However, individuals with MS have a tendency to neglect systematic screening for common health problems and to attribute any new symptom to MS. Therefore, it is essential that MS patients see a primary care physician on a regular basis and be referred to the appropriate specialty when needed. Also,

basic wellness recommendations (e.g., diet, exercise) can help improve general health as well as MS symptoms.

## CONCLUSION

MS is a complex, long-term, unpredictable, functionally and emotionally taxing disease. It is arguably one of the most difficult neurological diseases to manage. Needs vary widely between individuals and over time, and there are many circumstances in which a comprehensive approach involving rehabilitation may be beneficial. Simple rehabilitative strategies such as recommending a rollator or an AFO may make the difference between walking and not walking. However, rehabilitation is still underutilized in MS, and MS rehabilitation is not as well-defined as spinal cord injury or stroke rehabilitation. The principles commonly used for disease management can and should be applied to symptom management and rehabilitation: diagnose (or identify the problem), start appropriate treatment early, and monitor and adjust the treatment strategy over time.

# Rehabilitation of Persons with Parkinson's Disease and Other Movement Disorders

## INTRODUCTION

Parkinson's disease affects roughly 1% of the population older than age 50 in the United States, incidence increases with age, and the peak onset occurs in the sixth to eighth decade, making it one of the most common chronic diseases of adulthood (1). Life expectancy is near normal; however, there is increased risk for morbidity and mortality due to associated complications, such as falls, orthostatic hypotension, or aspiration pneumonia.

Rehabilitation has a vital and unique role in movement disorders. Parkinson's disease is a chronic, progressive, neurological disease, which at various stages and manifestations affects all aspects of a patient's functional state. The goal of this chapter is to review the clinical presentation and neuropathology of Parkinson's and other movement disorders, with specific emphasis on the collaborative process of rehabilitation. The disablement process in Parkinson's is based, just as in other medical and neurological disease states, on the continuum of impairments and how they affect functional limitations and subsequent disability (2,3). The impact of multifaceted treatment is covered in this chapter as well, placing high importance on the role of exercise with and without pharmacological management.

The *shaking palsy* or *paralysis agitans* was the description James Parkinson used in 1817 to represent what would later be referred to as "Parkinson's Disease," the progressive, central nervous system impairment that is characterized by the presence of two or more cardinal signs: bradykinesia, resting tremor, rigidity, and postural instability. The diagnosis of Parkinson's disease can be challenging and is first and foremost a clinical diagnosis. The typical individual afflicted with Parkinson's disease presents with symptoms on one side of the body, referred to as asymmetric onset. Typically, individuals with Parkinson's disease can be subdivided into two groups: those with a predominance of rigidity and akinesia, with minimal or no rest tremor; and those with rest tremor predominant disease. However, other signs and symptoms may be present as well (Table 26-1). Parkinson's disease can be incorrectly diagnosed as much as 25% of the time if based solely on clinical features and not on diagnostic trials, specifically responsiveness to

dopamine treatment (4,5). The rate of progression of Parkinson's varies significantly from one person to another.

Although the exact cause of Parkinson's is not known, environmental and genetic factors have been implicated. One theory regarding the pathogenesis of Parkinson's disease is that unidentified environmental triggers cause accelerated destruction of the dopamine-producing neurons in the substantia nigra in a genetically predisposed individual. Secondary parkinsonism refers to those disorders that have the same combination of signs and symptoms that are seen in primary Parkinson's disease but result from a clearly identifiable insult to the central nervous system. Examples of such insults include exposure to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (6–8), which causes the death of dopamine neurons and ischemic infarcts involving the vascular supply to the midbrain that can also result in the death of dopamine neurons. Dopamine-antagonist medications, (specifically antagonists of D2 receptors), such as the typical neuroleptics haloperidol and thioridazine, and other D2 antagonists, such as metoclopramide, have been known to exacerbate or even induce parkinsonism. Infectious conditions, such as St. Louis encephalitis, and von Economo's and other influenza-related encephalitides, have also been associated with secondary parkinsonism.

## ANATOMY AND PATHOPHYSIOLOGY

Motor impairment in Parkinson's and other movement disorders stems from a common principle: There is a disruption in the modulation of the cortical and subcortical structures of the brain. The anatomic structures involved in the control of movement are referred to as pyramidal and extrapyramidal structures, or motor cortices and the basal ganglia, respectively (9–12). A basic understanding of these structures and their physiology forms the basis of symptom-driven therapy in the management of patients with movement disorders.

The several interconnected nuclei of the basal ganglia make up a large portion of the extrapyramidal system. The

**TABLE 26.1 Clinical Presentations of Parkinson's Disease**

Clinical Signs and Symptoms of Parkinsonism	
Symptoms	Clinical Features
Positive phenomena	
Tremor	Most common symptom. Distal involvement frequency: 3.5 Hz. Suppressed by sleep and activity, increased by fatigue or stress. EMG: rhythmic alternating bursts in agonist and antagonist muscles.
Rigidity	Increase in muscle tone during passive limb movement equal through entire range of motion; increases if contralateral limb is engaged in volition.
Flexed posture	Dominance of progravity flexor muscles (bowed head, chin toward chest, kyphotic thorax, protracted shoulders, internally rotated arms, flexed elbows, knees, and hips).
Negative phenomena	
Bradykinesia	Slowness of movement, masked facies, decreased eye blinking, inability to move. Fatigue. EMG: delayed motor unit recruitment, pauses once recruited, inability to increase firing rate.
Loss of postural reflexes	Tendency to fall to the side (lateral pulsion) or backward (retropulsion); sitting <i>en bloc</i> (collapses in the chair when attempting to sit down).
Postural instability	
Freezing phenomenon	Transient inability to move.

EMG, electromyography; Hz, hertz.

Adapted from Jain SS, Francisco GE. Parkinson's disease and other movement disorders. In: DeLisa JA, ed. *Rehabilitation Medicine: Principles and Practice*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1988:1035–1056.

nuclear groups of the basal ganglia include the caudate and putamen (together called “the striatum”), the subthalamic nucleus (STN), internal and external portions of the globus pallidus (Gpi, GPe), and the pars compacta and pars reticulata of the substantia nigra (SNc, SNr).

The *primary afferent nuclei* of the basal ganglia are the striatum and the STN. The striatum receives excitatory input from the cerebral cortex, midline thalamic nuclei, hippocampus, amygdala, and primary olfactory cortex. The striatum also receives dopaminergic input from the substantia nigra pars compacta (SNc) and serotonergic input from the midbrain raphe nuclei. The *primary efferent nuclei* of the basal ganglia are the globus GPi and the substantia nigra pars reticulata (SNr). These output nuclei project inhibitory gamma-aminobutyric acid (GABA)-mediated control over the thalamus and brain stem targets (pedunculopontine nucleus). Basal ganglia output indirectly influences cortical activity by inhibitory control of the thalamus. A detailed hypothesis set forth by Mink (13) described that the net effect of basal ganglia activity during a voluntary movement is twofold: “Inhibition of competing motor patterns and a focused facilitation of selected voluntary movement pattern generators.” Physiologically, the substantia nigra and the globus pallidus tonically inhibit the motor nuclei of the thalamus, which have excitatory influences at the motor cortex. Pathologically, the thalamic motor nuclei are disinhibited, resulting in increased cortical motor output activity (Fig. 26-1). Electrophysiologic studies have demonstrated that the basal ganglia do not initiate or program movements but appear to modulate a motor pattern initially generated by cortical neurons (13). With the understanding that the essence of basal ganglia influence on motor activity is inhibitory control of the thalamus, the theoretic net effect of basal ganglia activity

on voluntary movement is the inhibition of competing motor patterns and the focused facilitation of the cortically selected voluntary movement (13).

**FIGURE 26-1.** Circuitry of direct and indirect pathways and pharmacology of the basal ganglia. The direct pathway projects gamma-aminobutyric acid (GABA)-mediated inhibitory input directly to the output nuclei of substantia nigra reticulata (SNr) and globus pallidus interna (GPi). The indirect pathway sends an inhibitory GABA projection to the globus pallidus externa (GPe), which subsequently projects GABA-mediated inhibitory input on the subthalamic nucleus (STN). The STN output to the SNr/GPi is an excitatory glutamate projection. *Solid arrows* reflect excitatory pathways and *dashed arrows*, inhibitory pathways. DA, dopamine; D1, D1 dopamine receptor; D2, D2 dopamine receptor; DYN, dynorphin; ENK, enkephalin; PPN, pedunculopontine nucleus; SNc, substantia nigra zona compacta; SP, substance P. Modified from Alexander GE, Crutcher MD, Functional architecture of the basal ganglia circuits: neural substrates of parallel processing (10).

## REHABILITATION AND COLLABORATION

Neurologists and, to some extent, primary care physicians largely oversee the care of persons with Parkinson's and medically manage the patient. What has become increasingly clear in neurological and neuromuscular disease management is the necessity of the multidisciplinary approach, in order to offer holistic and comprehensive medical and functional care of the patient. A rehabilitation team should ideally incorporate neurology, physiatry, physical and occupational therapy, speech and language pathology, social work, psychology and/or psychiatry, and nutrition. It, of course, promotes a patient-centered approach with collaboration of all disciplines with the expertise to diagnose and treat various impairments (14).

Physiatrists often see patients with movement disorders, mainly those with Parkinson's, in consultation. This practice may be in the form of a multidisciplinary clinic with neurologists, therapists, social workers, and psychiatrists or psychologists, or in a stand-alone physiatric practice. Physiatrists can be helpful for specific therapy prescription and analysis and treatment of gait abnormalities. Although a relatively low number of studies address the optimal therapeutic management plan, a collaborative effort by physiatrists and neurologists should logically provide the best therapeutic structure for the movement disorders population. Physiatrists who treat patients with various neurologic diagnoses should be able to assume a more active role in managing movement disorders.

The role of physiatry may be to assist with nonoperative orthopedic problems or basic musculoskeletal and pain impairments typical in this population. Physiatrists in the outpatient and inpatient settings collaborate and communicate with physical therapists, occupational therapists, and speech and language pathologists in order to optimize the function of the patient with a movement disorder. Therapists who subspecialize in Parkinson's treatment and other movement disorders are invaluable links between patient and physician. Therapists offer not only highly skilled assessments and treatments of functional impairments but also longitudinal education of the patient and family that is essential for carryover and functional gains.

Therapists and physiatrists may encounter a person with Parkinson's admitted to the rehabilitation unit for another condition, such as stroke, or after an orthopedic procedure or after the implantation of deep brain stimulators, which are used to treat some of the complications of Parkinson's disease (discussed later in this chapter) (15). These patients pose a unique challenge to the rehabilitation team, who are cognizant of baseline parkinsonian impairments and the additional neurological, orthopedic, or other impairment (16). One of the vital roles of the rehabilitation team is to help the patient and his or her primary medical or surgical team understand how the new illness or procedure will likely influence his or her preexisting parkinsonian impairments.

The team designs a rehabilitation program in order to set appropriate therapeutic goals. The deconditioning syndrome in and of itself certainly affects the hospitalized patient with a movement disorder while in the acute-care setting and can impact upon the patient's short- and long-term functional goals.

Nursing staff should be aware of the key importance of timely administration of anti-Parkinson drugs in order to minimize fluctuations in blood levels. Optimal pharmacological management impacts proper daytime participation with therapists and exercise (17). Those with Parkinson's are at risk for nutrition impairment, constipation, and low-energy states, and therefore a nutritionist or dietitian is required to focus on preparing the appropriate caloric and supplement needs for the patient.

## IMPAIRMENTS AND FUNCTIONAL LIMITATION IN PARKINSON'S

The concept of disability or disablement has been demonstrated in various ways, with the two most common being the International Classification of Impairments, Disabilities and Handicaps (ICIDH), and the Nagi (Saad Z. Nagi) framework in the 1960s. Nagi introduced the principle of "disablement," which is a process initiated with *pathology* leading to *impairment* that causes *function limitation* and in turn *disability*. What is intriguing about this framework is that disability can be positively affected at all four conceptual levels of the continuum. In Parkinson's, *pathology* resides in the substantia nigra at the cellular level and results in the inability to create sufficient dopamine. One's *impairment* may be muscle rigidity or bradykinesia, for instance, with *functional limitation* manifesting in gait dysfunction. *Disability* is the inability to optimally participate in community activities or carry a job, which occurs due to the functional limitation (2,3).

Physiatrists and the rehabilitation team assist in the care of persons with Parkinson's by managing the various impairments that result from the condition (Tables 26-2 and 26-3).

**TABLE 26.2** Impairments Resulting From Parkinson's Disease

Motor
Gait
Movement initiation and execution
Bradykinesia
Tremor
Rigidity
Sensory/pain
Autonomic dysfunction
Orthostatic hypotension
Constipation
Cognitive
Difficulty in switching from one task to another
Behavioral and affective
Depression
Anxiety

Gastrointestinal
Dysphagia
Constipation
Bladder dysfunction
Sexual dysfunction

**TABLE 26.3** Therapeutic Plan for Patients With Parkinson's Disease**Medical and Nursing**

Firm bed to decrease contractures and improve bed mobility  
 Gradual changing of positions, elastic stockings, abdominal binder, sodium tablets, and possibly pseudoephedrine, midodrine, and/or fludrocortisone for orthostasis  
 Regular meals with proper diet (low protein); nutritional consultation  
 Measure vital capacity and enforce incentive spirometry to prevent atelectasis and pneumonia  
 Bowel program for gastrointestinal hypomobility (stool softeners, bulk-forming agents, cisapride, and suppositories may be required)  
 Bladder evaluation and urodynamics; anticholinergics (e.g., oxybutynin chloride [Ditropan]) for hyperreflexic bladder  
 Artificial tears for lack of blinking  
 Sexual dysfunction evaluation  
 Anticholinergic medications before mealtime to help facilitate oral and pharyngeal movements

**Physical Therapy**

Relaxation techniques to decrease rigidity  
 Slow rhythmic rotational movements  
 Gentle range-of-motion and stretching exercises to prevent contractures, quadriceps and hip extensor isometric exercises  
 Neck and trunk rotation exercises  
 Back extension exercises and pelvic tilt  
 Proper sitting and postural control (static and dynamic); emphasize whole body movements  
 Breathing exercises stressing both the inspiratory and expiratory phase  
 Functional mobility training, including bed mobility, transfer training, and learning to rise out of a chair by rocking; may require a chair lift  
 Stationary bicycle to help train reciprocal movements  
 Training in rhythmic pattern to music or with auditory cues such as clapping may help in alternating movements. Standing or balancing in parallel bars (static and dynamic) with weight shifting, ball throwing  
 Slowly progressive ambulation training (large steps using blocks to have patients lift legs, teaching proper heel-to-toe gait patterns, feet 12–15 in. apart, arm swing; use inverted walking stick, colored squares, or stripes as visual aids)  
 Use of assistive devices (may need a weighted walker)  
 Aerobic conditioning (swimming, walking, cycling)  
 Frequent rest periods  
 Family training and home exercise program

**Occupational Therapy**

Range-of-motion activities of upper extremity with stretching  
 Fine motor coordination and training, hand dexterity training using colored pegs or beads  
 Hand cycling to help train reciprocal movements  
 Rocking chair to help with mobilization  
 Transfer training  
 Safety skills  
 Adaptive equipment evaluation, including Velcro closures, raised toilet, grab bars, eating utensils with built-up handles, and key holders  
 Family training and home exercise program

**Speech**

Deep breathing and diaphragmatic breathing exercises  
 Articulatory speech training for dysarthria  
 Facial, oral, and lingual muscle exercises  
 Swallowing evaluation, including a modified barium swallow as needed  
 Teaching compensatory strategies for safer swallowing

**Psychology**

Psychological support for patient, family, and caregivers  
 Cognitive assessment

Adapted from Jain SS, Francisco GE. Parkinson's disease and other movement disorders. In: DeLisa JA, ed. *Rehabilitation Medicine: Principles and Practice*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1988:1035–1056.

This section highlights ways that rehabilitation professionals can help minimize the impact that these impairments, and therefore function limitations, have upon well-being and disability of those with Parkinson's.

### Gait Dysfunction

Gait dysfunction is the primary presenting symptom in as many as 18% of patients with Parkinson's disease (18,19). Persons with Parkinson's report that one of the leading causes for diminished quality of life is difficulty walking (20). Shortened step length is the focal disturbance of gait in a person with Parkinson's, and the classic gait pattern is characterized by shuffling (21,22). Reduced hip, knee, and ankle flexion angles, decreased arm swing, limited trunk rotation, and increased forward flexed trunk are typical kinematic changes in gait among persons with Parkinson's disease. Parkinsonian gait becomes progressively inefficient and unstable as a result of multiple impairments (23,24). There are two stereotypical variations of parkinsonian gait patterns. Many persons demonstrate changes in the fluidity of gait with episodes of hesitation to initiate gait or instances of "freezing" when the person stops and cannot initiate movement while walking (25). These difficulties in performing efficient gait patterns are often observed when the person is turning around, walking through a doorway threshold, or stepping around or over objects (23,26,27). The second parkinsonian gait pattern is festination, characterized by small steps increasing in speed and frequency with a forward trunk posture (26). These gait abnormalities place persons with Parkinson's at varying risk for loss of balance or falls (24,28).

Although people with Parkinson's may be able to perform straight-line walking, their overall gait is hampered by hypokinesia, rigidity, postural imbalance, and the fear of falling, especially in advanced stages of the disease (24,29–31). Deficits have also been implicated, thus aggravating the problem and may be the reason why people with Parkinson's disease rely strongly on visual cues (32,33). The loss of proprioceptive feedback from the knee extensor load receptors is suspected to cause a reduction in the activation of leg extensor muscles (34). Other problems

that contribute to the gait abnormality include impairment in programmed muscle activation in the lower limbs and diminished postural reflexes (33). These impairments result in progressive difficulty adapting postural responses and stability during gait, especially on uneven surfaces (24,33,35–37).

During early stages of Parkinson's, *primary* impairments of hypokinesia, rigidity, proprioceptive deficits, decreased postural reflexes, and movement execution may have subtle effects on gait. During progression of the disease, the primary impairments are typically magnified and result in new *secondary* impairments (Table 26-4) (38). Muscle weakness due to the disuse and contractures from rigidity are examples of secondary impairments that further contribute to gait dysfunction. These abnormalities affect balance, alter gait, and increase the patient's risk for falls (24,28). Another factor contributing to gait instability is orthostatic hypotension, which will be discussed further in this section.

Gait dysfunction in patients with Parkinson's may be due to either the disease itself or as a side effect of pharmaceutical therapy (see Table 26-4). Levodopa therapy affects parkinsonian gait and movement, in that although the medication may facilitate gait during the "on" phase, deterioration may be seen as part of motor fluctuations during the "off" state. Its effect is largely due to the control of force and amplitude of limb movement, rather than improved automaticity or rhythmicity (39). Levodopa may also cause dystonia, which can negatively affect ambulation.

Direct and secondary impairments of Parkinson's can lead to further decline if patients *respond* to these impairments and limitations by decreasing activity levels. This results in further muscle weakness, joint contractures, and worsened endurance. Discussion with the rehabilitation team and prompt referral to therapy can facilitate early treatment approaches to "break the cycle" and prevent resulting functional limitation in gait and other activities. Advances in technology are exploring ways to help monitor changes in gait and functional mobility in the home environment among persons with Parkinson's using wearable sensors (40,41). In the future, such devices should offer clinicians the ability to titrate medication and make referrals to appropriate therapies based on these objective data.

**TABLE 26.4** Gait Disturbance in Parkinson's Disease

Gait Disturbance	Parkinsonian Direct Impairment
Shuffling gait pattern: Decreased step and stride length, decreased cadence and velocity	Bradykinesia and hypokinesia; movement initiation and execution impairment
Festination	Impaired automatic motor task performance; movement execution impairment; impaired postural responses
Stooped (flexed) posture	Rigidity
Freezing, "start hesitation"	Impaired automatic motor task performance; hypokinesia; movement initiation and execution impairment
"Cautious" gait (fear of falling)	Impaired postural responses; rigidity
Impaired balance and unsteadiness due to lightheadedness	Impaired postural responses; orthostatism; ANS impairment
Dystonia, dyskinesia	Medication effect; Parkinson's disease—direct impairment related movement disorder

## Movement Initiation

The person with Parkinson's typically possesses slow movement initiation that may result from delayed activation of the motor cortex, impeding one's ability to initiate and execute normal movement (42). Although the corticospinal system is intact, the abnormal motor commands result in bradykinesia in the implementation and execution of a motor task. These impairments are exacerbated with high-complexity tasks. Highly refined motor activities such as handwriting require switching between motor components, and the limited ability of people with Parkinson's to adapt to changing task conditions makes this difficult. Indeed, it appears that slow initiation of movement may be a strategy adopted by those with the disease to facilitate motor tasks (43,44).

## Dyskinesia and Dystonia

Dyskinesias, the excessive movement of muscles in the trunk or limbs that cannot be controlled voluntarily, are a common complication that typically develops after 7 or 8 years of levodopa therapy. It is thought to result from a complex interplay between the imperfect supplementation of dopamine, in the form of oral carbidopa/levodopa tablets, and the underlying, progressive loss of dopamine neurons that is the hallmark of Parkinson's.

Most commonly, dyskinesias are seen when the plasma concentration of levodopa is at its highest. This is referred to as "peak-dose" dyskinesia. It is believed to result from abnormal neuronal firing patterns in response to pulsatile stimulation of the dopamine receptors (45). In the early stages, it can be managed by reducing the dose of levodopa or taking levodopa less frequently. However, this typically results in a worsening of the symptoms of Parkinson's, such as rest tremor, bradykinesia, and rigidity. It is important to remember that if dyskinesias are relatively mild and not bothersome or dangerous to the patient, then most people prefer to move too much rather than too little. If dyskinesias become large in amplitude, to the extent that they risk injury to the patient, then they must be treated. Treatment options include decreasing the dose of levodopa, decreasing the frequency with which levodopa is taken, and adding amantadine to the medication regimen.

Dystonia, the involuntary contraction of a single muscle or multiple muscles that cause an abnormal posture, is also commonly seen in those with Parkinson's. The most common site for dystonia in those with Parkinson's is the foot. Typically, at the end of a dose of levodopa, when plasma concentrations are at their lowest, the foot begins to contract with flexion of the toes and inversion of the entire foot. With the ingestion of another dose of levodopa, the dystonia is relieved. Dystonia may also occur as a peak-dose effect, when plasma concentrations of levodopa are at their highest. Unfortunately, peak-dose dystonia is not easily treated. If dystonia presents as a focal problem, such as involving the neck muscles or the facial muscles, then local therapy with botulinum toxin injection is an option.

## Orthostatic Hypotension

Up to 20% of the population with Parkinson's may experience orthostatic hypotension, which may be the result of central or peripheral mechanisms. This usually results from sympathetic outflow dysfunction that leads to impaired peripheral vasoconstriction. Intravascular volume depletion due to poor fluid intake or other mechanisms magnifies the problem. Because Parkinson's usually occurs in the elderly, other age-related medical conditions, such as cardiovascular diseases and use of drugs that cause hypotension, should be taken into consideration (46–48).

Lifestyle modification and education are important aspects of treatment. For example, patients should be counseled that warm or hot baths increase peripheral vasodilation and may contribute to orthostasis. A heavy meal may also result in splanchnic vasodilation and "steal" blood volume from elsewhere. Excessive straining while defecating and other tasks inducing the Valsalva maneuver should be avoided, and high-fiber diets and stool softeners should be incorporated as well. Nonpharmacologic methods include the use of compression leg stockings and abdominal binders. Management also includes eliminating unnecessary antihypertensive drugs or other medications that may cause hypotension and (47) potentially providing blood pressure support with fludrocortisone or midodrine.

## Gastrointestinal Problems

### Swallowing Dysfunction

Dysphagia typically results from loss of lingual control and inability to propel the bolus due to delay in the contraction of pharyngeal muscles. Up to 75% of people with Parkinson's experience dysphagia, and esophageal dysmotility may also occur (49–54). Abnormalities in striated muscles under dopaminergic control and smooth muscles under autonomic influence contribute to this complicated impairment. Videofluoroscopic swallowing evaluations help to determine which specific phases of swallowing are impaired. Modified barium swallows under fluoroscopy have shown that the most common abnormalities are motility problems, hypopharyngeal stasis, aspiration, and deficient positioning of the esophagus (55,56).

A speech pathologist may help by teaching oral-motor exercises and providing education on compensatory strategies to prevent penetration and aspiration. A recent randomized controlled trial evaluating the efficacy of the chin-tuck maneuver versus thickened liquids only for Parkinson's and dementia patients demonstrated that a chin-tuck cohort and thickened-liquids-only group equally prevented the development of pneumonia at 3 months follow-up; however, aspiration during videofluorographic assessment was prevented more readily with thickened liquids only (not using chin-tuck) (57). Importantly, when an individual cannot meet his or her caloric and fluid requirements, a gastrostomy feeding tube should be considered.

### Nutrition

Parkinson's patients are at risk for weight loss and should be closely evaluated for nutritional losses (52). Protein intake should be monitored and limited, in that amino acids compete with levodopa for absorption. Clinicians may advise patients to take levodopa 1 hour before or after a meal in order to facilitate proper absorption. This is of particular concern to those in the late stages of the disease who have severe dyskinesias. Vitamin supplements should be considered for those who are unable to have well-balanced and adequate nutrition. The precise amount of vitamin supplementation needs to be monitored carefully because vitamin B6 supplementation may result in reduced absorption of levodopa from the intestines (58).

### Delayed Gastric Emptying

Parkinson's patients experience early satiety or may experience nausea and vomiting due to delayed gastric emptying. Reduced peristalsis and gastroesophageal reflux present as complaints of "heartburn" or indigestion. This also puts the patient at risk for poor nutritional intake and therefore can exacerbate absorption of levodopa and other medications. Anti-Parkinson drugs themselves may also contribute to gastric emptying. On the other hand, pro motility agents, such as metoclopramide (Reglan), may worsen dyskinesias (55).

### Constipation

Constipation is a frequent obstacle in people with Parkinson's. Its cause is multifactorial, including altered sympathetic innervation of the gastrointestinal tract, various concomitant medications, overall limited mobility, and impaired hydration. Nonpharmacological treatments include adequate hydration, increased physical activity, and high-fiber diets. If these tactics do not resolve the problem, the use of a daily osmotic agent such as miralax or lactulose can be helpful.

### Bladder Problems

One of the most common and earliest bladder abnormalities in patients with Parkinson's is nocturia (45). This, along with urgency and frequency, is thought to result from detrusor hyperreflexia. In some patients, detrusor *hyporeflexia* and urinary sphincter problems occur. Urodynamic studies may be needed to diagnose the nature of the problem before appropriate treatment can be instituted. Management includes timed voiding, intermittent catheterization, and pharmacologic agents, such as peripherally acting anticholinergics. Redistribution of fluid intake, such that the bulk of fluid ingestion occurs earlier in the day, may be necessary to avoid nocturia.

### Cognition

The onset of the cognitive symptoms in those with Parkinson's is usually slow. The cognitive domains that are most often affected include attention, memory and learning, executive functions, and visual-spatial functions. Verbal function and the ability to reason seem to be spared, although information processing may be slower. In a study of people who were nearly

diagnosed with Parkinson's disease, researchers found that 36% showed some form of cognitive impairment (59). Specifically, these patients had difficulty with visual processing and executive functioning.

There is no specific medical treatment for the cognitive dysfunction seen in those with Parkinson's. However, minimizing the use of medications that may cause confusion is an important precaution, as those with baseline cognitive dysfunction are more likely to become transiently worse if treated with medications that are known to cause some confusion as a side effect.

### Psychiatric Manifestations

Many people with Parkinson's experience depression. About half of the Parkinson's patients have *dysthymia*. Estimates of prevalence of depression in those with Parkinson's disease have ranged from 40% to 50% (60). There are unique characteristics to the depression found in those with Parkinson's. Depressed patients with Parkinson's experience higher rates of anxiety, are more often sad without feeling guilt or self-blame, and have lower rates of suicide despite higher rates of suicidal thoughts. The most commonly prescribed antidepressants for people with Parkinson's disease are the selective serotonin reuptake inhibitors (SSRIs). Dopamine replacement, the cornerstone of treatment for Parkinson's disease, can also result in psychiatric complications (61). As levodopa replacement is increased to ease worsening motor symptoms, some people may experience hallucinations, delusions, agitation, mania, or confusion.

As many as 40% of people with Parkinson's experience anxiety and panic attacks. They may result from central neurotransmitter dysfunction or as a reaction to Parkinson's and its complications. Thus, management includes optimization of an anti-Parkinsonian drug regimen, discontinuation of offending drugs, and institution of anxiolytic therapy.

Depression occurring in Parkinson's has been shown to be independent of disease severity and duration (62–65). The prevalence of depression in the Parkinson population has been shown to be roughly 30% as indicated by a 1996 review of 45 studies. Twenty percent of persons demonstrated moderate to severe depression on the Beck Depression Index in a community-based study (66). Many features of depression, such as psychomotor retardation, stooped posture, lack of initiation, decreased affect, poor sleep and appetite, are in fact similar to symptoms of Parkinson's (67,68). Thus, depression in people with Parkinson's may be underrecognized due to some of the similar somatic complaints that exist in both conditions. Those with depression and Parkinson's typically have more anxiety and suicidal ideation and less guilt. It is unclear as to the extent to which "reactive depression," or one's depressive symptoms as related to the chronic disease, exists as compared to neurochemically based or intrinsic depression; however, it is likely that both play a role. Those with Parkinson's indeed exhibit more depressive symptoms than do other chronic disease counterparts, showing that intrinsic processes likely predominate in Parkinson's (69,70). Regarding

treatment for depression in Parkinson's, there is limited data pointing to specific medications. One report showed efficacy, albeit with a less desirable side effect profile, in a tricyclic antidepressant versus fluoxetine trial (71). Ideally, patients should be followed in a multidisciplinary clinic where Parkinson's-specific counseling can be offered, as this can be a crucial adjunctive treatment option.

### Pain and Parkinson's

Roughly two thirds of people with Parkinson's experience pain during the course of the disease (72). Pain in patients with Parkinson's is either primary (central processes) or secondary to other conditions. Primary pain typically presents as an aching pain in the affected limb. It is more likely to occur in younger patients with predominant dystonia and akinesia and involves the side more affected by rigidity.

Limb rigidity is the most common cause of pain in patients with Parkinson's and can be incorrectly diagnosed as cervical or lumbar radiculopathy (73). Many people with Parkinson's have "pseudo-rheumatic disorders" that result in limb and joint deformities, and mechanically derived pain. Fractures should be ruled out whenever a person with Parkinson's experiences a fall. Patients may also suffer from restless leg syndrome, a condition characterized by an unpleasant sensation in the legs accompanied by an overwhelming need to stretch or walk (72). Other manifestations of primary pain in people with Parkinson's are headaches, characterized by deep, throbbing, occipital or neck pain. Oral and genital pain has also been reported (72).

Typical analgesics may not be effective. Treatment of the parkinsonian symptoms pharmacologically and nonpharmacologically, with the goal being to improve mobility and flexibility of the affected limbs, can help alleviate primary pain. Secondary pain may present as abdominal discomfort resulting from constipation, or shoulder and limb pain due to complex regional pain syndrome (formally known as reflex sympathetic dystrophy, RSD), an autonomic nervous system dysfunction. Painful limb dystonia is also an important cause of secondary pain and may be helped by botulinum toxin injections.

## TREATMENT

### Pharmacological Management

The introduction of levodopa several decades ago was an important event in the history of management of Parkinson's disease. The availability of newer medications contributes to the evolution of pharmacologic therapy for the disease. To date, all available treatments help to control the symptoms of Parkinson's disease but do not delay or halt its progression.

Experts agree that symptomatic therapy for Parkinson's disease should be initiated when the symptoms of Parkinson's disease are severe enough to result in functional impairments that affect the individual's ability to move around safely, perform activities of daily living (ADL), or maintain employability (19).

Levodopa is commercially available as Sinemet, which is a combination of levodopa and carbidopa. The latter is a

decarboxylase inhibitor that prevents the peripheral conversion of levodopa to dopamine. In the absence of adequate carbidopa, levodopa may result in peripheral side effects, such as nausea, vomiting, and hypotension. A sustained-release preparation, which decreases fluctuations in blood level of the drug but is not always reliably absorbed in the intestines, is also available.

Dopamine agonists are another group of drugs that have been used to treat individuals with Parkinson's disease. Unlike levodopa, dopamine agonists do not need to be converted to an active product. They directly stimulate dopamine receptors. In addition, dopamine agonists appear to have longer duration of effect than does the immediate-release form of levodopa, thus providing more sustained stimulation of dopamine receptors. The older dopamine agonists, such as bromocriptine and pergolide, have been used as an adjunct to levodopa. The most serious side effect associated with their use is cardiac valve abnormalities. Because of this serious potential side effect, and the development of newer, more specific dopamine agonists, these drugs are not used as frequently as they once were. The newer dopamine agonists include pramipexole and ropinirole (74). Pramipexole and ropinirole are selective agonists of the D2 and D3 receptors that have been shown to be effective in early and advanced Parkinson's disease (75–80).

Amantadine, an antiviral agent, has also been used to reduce dyskinesias. Although its exact mechanism is yet to be elucidated, it is known to have dopaminergic effects by promoting synthesis and preventing reuptake of dopamine, increasing dopamine release, and stimulating dopamine receptors. Up to 10% of patients taking amantadine report dizziness or insomnia, and up to 5% may experience constipation, diarrhea, or nausea. Headache, irritability, vivid dreams, and anxiety have also been described with regular use (81–85).

Anticholinergic agents, such as trihexyphenidyl and benztropine, have also been used to treat the symptoms of Parkinson's disease. The rationale for their use in patients with Parkinson's disease is to restore the imbalance of dopamine and cholinergic transmission in the brain (85). However, with the advent of the newer dopamine agonists, anticholinergic agents are no longer used as commonly as they once were.

Another class of drugs, the catechol-*O*-methyl transferase (COMT) inhibitors, such as entacapone and tolcapone, are used as adjuncts to carbidopa/levodopa treatment. They prevent the metabolic conversion of levodopa to 3-*O*-methyldopa peripherally by the enzyme COMT. Thus, there is increased availability of levodopa, resulting in enhanced benefits of levodopa in individuals with Parkinson's disease (86). Table 26-5 summarizes these medications' mechanisms of action, dosing, uses, and side effects.

### Deep Brain Stimulation

Surgical procedures (Table 26-6) had once been the first-line therapy for patients with Parkinson's disease, but with the introduction of levodopa in the late 1960s, surgical treatments have become less attractive because of the side effects and complications. However, patients with advanced Parkinson's disease often develop significant motor complications (freezing,

**TABLE 26.5** Pharmacotherapy of Parkinson's Disease

Drug	Mechanisms of Action	Usual Dosing	Side Effects	Other Comments
Levodopa	Levodopa activates D1 and D2 dopamine receptors in the brain. Carbidopa is a peripheral dopa-decarboxylase inhibitor. It increases therapeutic potency and decreases gastrointestinal side effects of levodopa	Sinemet (levodopa/carbidopa) 25/100 titrated upward to achieve desired clinical effects (dosage strengths available: Sinemet, 10/100, 25/100, 25/250; Sinemet-CR, 25/100, 50/200)	Nausea, vomiting, hypotension (usually due to inadequate doses of carbidopa); dyskinesias; motor fluctuations; neuropsychiatric problems (e.g., confusion)	Cornerstone of treatment for Parkinson's disease
Dopamine agonists: Bromocriptine Pergolide Cabergoline Pramipexole Ropinirole	Stimulate dopamine receptors	2.5–40 mg/d 0.1–5 mg/d 0.5–1 mg/d 1.5–4.5 mg/d 0.75–24 mg/d	Similar to levodopa; bromocriptine may cause red, inflamed skin (St. Anthony's fire), which is reversible on drug discontinuation	Reduced incidence or levodopa-related side effects; selective stimulation of dopamine receptor subtypes; potential neuroprotection; limited antiparkinsonian effect
Amantadine	Promotes synthesis and prevents reuptake of dopamine; increases dopamine release; stimulates dopamine receptors	100 mg every other day for 1 wk, with subsequent dose increase to up to 100 mg tid	Insomnia, confusion, hallucination, ankle edema, livido reticularis	Limited clinical efficacy
Anticholinergics: Trihexyphenidyl	Restore imbalance between dopaminergic and cholinergic neurotransmitters	0.5–1 mg bid and gradually increased to 2 mg tid	Significant cognitive (e.g., confusion, hallucination, memory impairment, etc.) and peripheral antimuscarinic side effects (e.g., dry mouth, blurred vision, constipation, etc.)	Limited clinical efficacy
Benzotropine		0.5–2 mg bid		
COMT inhibitors: Entacapone		200 mg/dose (up to 1,600 mg/d)	Dyskinesia Diarrhea	Increases levodopa availability; smoother levodopa plasma levels, thus, reducing levodopa-related side effects
Tolcapone		100–200 mg tid	Liver toxicity/(tolcapone)	
Selegiline hydrochloride (Deprenyl or Eldepryl)	MAO-B inhibitor	5 mg at breakfast and 5 mg at noon	Fulminant liver failure Hypertensive reactions may occur if taken with theophylline, ephedrine, carbidopa/levodopa and foods containing tyramine	May potentiate levodopa; some clinicians use it as monotherapy in early IPD. May delay the need for levodopa for about 9 mo. Used with levodopa to potentiate its effects and reduce the dose of levodopa
Rasagiline (Azilect)	MAO-B inhibitor	5 mg daily		

COMT, Catechol-*O*-methyl-transferase; IPD, idiopathic Parkinson's disease.

dyskinesias that cannot be managed with medication alone (87). The development of deep brain stimulation (DBS), which allows a neurosurgeon to insert programmable leads into a discrete nucleus of the basal ganglia, has led to a resurgence of surgical treatment for advanced Parkinson's disease (88,89).

DBS was introduced by Benibid et al. in the late 1980s as an alternative surgical treatment for patients with Parkinson's disease (90). There are many published reports about the clinical effect of DBS, and its use has emerged from being "experimental" to being part of the standard armament in the treatment of Parkinson's disease. The procedure involves passage of a needle through brain tissue to place electrodes at specific target sites that deliver stimulation to a specific target in the basal ganglia, which is responsible for its clinical effects (91,92).

DBS simulates the surgical ablative procedures with high-frequency stimulation of certain target tissue *without* making a destructive lesion in the brain. It offers several advantages over ablative procedures: it accomplishes bilateral stimulation with minimal side effects; parameters can be adjusted postoperatively to improve symptoms or minimize side effects; and it is reversible so that the patient can still benefit from future treatment options. The disadvantages include risk for hemorrhage with needle passage, complications related to the device such as mechanical failure (lead placement or battery changes), and infection. The extent of stimulation is adjusted gradually, in the months following the surgery, in an outpatient setting.

The most commonly targeted site for DBS is the STN. Stimulation of the STN allows patients to spend a greater part of their day with minimal rigidity and rest tremor, while on lower doses of anti-Parkinson medication. Currently, research is being done to determine if stimulation at other sites, such as the pedunculopontine nucleus, would be beneficial for treating the postural instability seen in those with Parkinson's disease (93–96). DBS is indicated in patients who have on/off fluctuations with severe immobility when "off" but continue to respond to levodopa and/or have levodopa-induced dyskinesias.

### Fetal Cell Transplantation

Fetal cell transplantation offers the potential to replenish the supply of dopaminergic neurons in the substantia nigra. In a recent

study where human embryonic dopamine neurons were transplanted into the brains of patients with severe Parkinson's disease, there was no significant, long-term improvement in symptoms (97). A critical question, which remains unanswered, is how to ensure that the implanted cells form the proper connection with other cells in the brain. There are many obstacles to successful implantation, including identifying optimal transplant variables and target sites, and ethical concerns of using fetal cells (98).

## THE ROLE OF EXERCISE AND PHYSICAL THERAPY

The rehabilitation team must always keep in mind that treatment with therapeutic exercise is directed to the *person*, not solely the *Parkinson's*. Whether our patients with movement disorders are free of comorbidities, or whether they have congestive heart failure or diabetes, the general health of the patient certainly affects the "functional health" of the patient. Exercise has played a major role in attenuating hypertension and reducing the rates of coronary artery disease, stroke, and type II diabetes mellitus (99,100). Aerobic exercise lowers blood viscosity, which in turn increases oxygen transport to vital organs, especially the brain. Exercise has repeatedly demonstrated positive effects on depression, anxiety, sleep, and general well-being (101). Of key importance especially in the elderly and postmenopausal women populations is the known benefit of weight-bearing and resistive exercise with respect to decreasing the onset of osteopenia (102,103).

In recent years, studies have emphasized the importance of exercise in neuroplasticity. There is evidence that exercise has protective benefits from the *onset* of Parkinson's. A part of this process is likely that the brain is able to receive more oxygen as a result of exercise. Animal work has revealed that when subjects are exposed to MPTP, in order to artificially induce parkinsonism, exercise alone and exercise along with learning tasks and socialization protect against development of the symptoms (104). This effect may be the result of increased global oxygenation of the brain, in addition to increased amounts of neurotrophic factors, which are thought to limit cell death while fostering new cell growth, in the setting of aerobic exercise (105).

How does exercise promote neuroplasticity in Parkinson's? Some basic concepts have been proposed: The neurons in the striatum that produce dopamine are highly "sensitive" to bursts of either activity or inactivity; therefore, there is a "use it or lose it" principle involved. Also, motor learning may occur more substantially if in the setting of "rewarding activities," in that dopamine production can be reward based. In addition, synaptic activity and neuron structural changes are optimized with complicated and intense activities. Lastly, and of key intrigue to all patients and clinicians involved in Parkinson's, when exercise is introduced at the earliest stages in Parkinson's, its progression may be slowed (106).

Investigators have also noted that exercise can increase levels of dopamine and that increased frequency, intensity, and duration of exercise influence these systemic levels (107). Physical exercise has also been shown to boost dopamine levels

in the striatum and is thought to increase due to a calmodulin-dependent pathway, in that experiments have revealed increased serum calcium levels in the brain as a result of exercise (108).

A large prospective study of more than 125,000 men and women investigated the relationship of physical activity and risk of Parkinson's disease (109). The study reported results from data collected from mailed questionnaires between 1986 and January 2000. While no clear association was found among the women studied, the investigators reported that men who performed strenuous exercise  $\geq 10$  months a year during their early adult life had 60% lower risk of having Parkinson's disease than men who regularly exercised  $\leq 2$  months a year (109). Ongoing studies are being performed to determine if moderate-intensity exercise will reduce the progression of Parkinson's disease (110).

During the early stages of Parkinson's disease, persons often are able to continue their current aerobic exercises or start programs with guidance from local fitness centers. Physiatrists can assess whether the patient is safe to exercise at such a facility with or without a physical therapist's evaluation and make the appropriate referrals. Aerobic exercises such as swimming, stationary bike riding, walking (outdoor or treadmill), and dance classes promote overall health benefits and, in particular, endurance (111–114). As with any adult, in particular those more than 40 years of age, prescribing any aerobic program should include cardiovascular screening. Abnormal cardiovascular reflexes are common among persons with Parkinson's disease. Orthostatic hypotension, cardiac arrhythmias, and exercise-induced hypotension can coexist with Parkinson's disease (115). Routinely monitoring patients allows proactive referrals to rehabilitation therapies to maximize capabilities and ideally slow the rate of loss of function ability through early interventions of strengthening and flexibility exercises as well as any adaptive equipment or assistive device needs. Similarly, routine monitoring of Parkinson's disease symptoms also promotes early recognition for speech and swallowing exercise and therapy needs.

Emphasis on maintaining safe, independent mobility is paramount. As rigidity and postural instability increase,

modifications to aerobic exercise become necessary to prevent falls. Rigidity in the trunk and neck limits normal upper trunk and lower trunk rotation during gait, which contributes to less efficient gait patterns and decreased gait speed. The reduction in neck range of motion may also contribute to reduction in balance control (23). Forward trunk flexion and stooped head may contribute to festinating gait patterns.

Several studies using various visual markers, stationary and mobile, have been performed showing improvement in step length and velocity (116,117). Studies using visual cues have been valuable in introducing more methods for rehabilitation specialists to enhance treatment effectiveness. Unfortunately, implementation of set, stationary visual cues for improving gait among persons with Parkinson's has limited carryover and is difficult to reproduce when ambulating in the community.

Auditory and other somatosensory cues may be helpful as well because they bypass the diseased basal ganglia (31,118,119). Continued research in the field of rhythmic auditory stimulus (RAS) has provided new evidence of the benefits of improving gait and limiting freezing episodes when listening to music or metronome-based rhythm. The use of RAS and visual and tactile rhythm cues has been investigated for portable home gait-training use (30,120).

Although traditionally results of the trials in the efficacy of exercise on Parkinson's have been mixed, a recent review of the literature demonstrated that upon reviewing 14 randomized controlled trials with "moderate" quality of study, exercise was considered efficacious in physical functioning, health-related quality of life, strength, balance, and gait performance. The evidence in this analysis neither supported nor refuted the propensity to reduced falls and depression (104). The benefit of resistance exercise has long been established in other populations, with its role in increasing muscle mass, function, and strength and promoting bone health, and not until recently have researchers assessed the benefit on Parkinson's (3). Five resistance interventions were evaluated between 2000 and 2007, revealing an overall increase in strength, balance, and muscle mass (57). Table 26-7 lists some of the fundamental

**TABLE 26.7** Studies on Effects of Therapy and Exercise on Parkinson's Disease

	Participants	Method	Intervention	Outcome Measure
Palmer et al. (1986) (37)	14 (12 males; mean age, 64.9 y)	Randomized parallel group design	Karate exercise ( $n = 7$ ) vs. stretch exercises ( $n = 7$ )	Parkinson's disease motor battery; ADLs; grip strength; motor speed and coordination

trials on the efficacy of therapy and exercise on Parkinson's disease between 1986 and 2007.

### Specific Exercises for Parkinson's

Specific exercises should include strengthening of back and neck extensor, hip musculature, and abdominal muscles in order to promote a more upright posture. Similarly, emphasis on stretching trunk flexor muscles, hamstrings, and heel cords will promote better posture and muscle length balance. These muscle groups are important for promoting good posture for swallowing and speaking as well as for safe mobility.

Designing and updating exercise programs to meet the changing needs of each person with Parkinson's disease allow the patient and the rehabilitation team the best opportunity to maximize functional ability throughout the progression of the disease.

Physical therapy, emphasizing gait retraining and motor control relearning, may help overcome postural instability. The individual can be trained to focus on foot positioning to provide a more stable base for posture and gait. Other helpful techniques include teaching the individual to turn around in a wide arc, rather than pivoting, in order to avoid the risk for loss of balance and postural stability, thus decreasing the risk for falls. Instructing the individual consciously to take longer steps with the help of verbal and visual (object) cues may help overcome the effects of freezing and festination. With the help of a neurologic music therapist, the physical therapist can provide exercises in a rhythmic fashion, that is, movements coupled with musical or drum-beating rhythm. Other specific exercises should include aerobic conditioning to improve endurance, strengthening of back extensor and abdominal muscles in order to promote a more upright posture, and stretching of trunk flexor muscles.

Assessment for an assistive device for gait will also be performed by the physical therapist. Depending on the predominant gait abnormality, a cane or rolling walker may offer stability while encouraging natural, fluid gait movement. The *U-Step* walker (InStep Mobility, Inc. <http://www.ustep.com/walker.htm>) has had increasing popularity in advanced Parkinson's. In the middle of a rolling walker, there is a laser beam that projects in front of the patient for guidance and cuing to help prevent freezing. Instructing the individual consciously to take longer steps with the help of verbal and visual (object) cues may help overcome the effects of freezing and festination.

### OTHER MOVEMENT DISORDERS

The most common difficulty rehabilitation professionals encounter when faced with movement disorders is in correctly classifying them (Table 26-8) (121) (e.g., *Is this dystonia or simply spasticity? Does this patient have a tic or focal myoclonus?*). In contrast to the importance of correct classification, identifying the underlying etiology of a given movement disorder (e.g., ischemic, anoxic, traumatic) is often less important in its management. Regardless of the specific cause, the individual

**TABLE 26.8** Movement Disorders

<i>Chorea</i>
Brief, rapid, forceful, dysrhythmic, discrete, purposeless, flinging of limb
<i>Athetosis</i>
Slow, writhing movements and inability to maintain position of limb or body part
<i>Ballismus</i>
Large amplitude, flinging movement of limb (usually proximal)
<i>Dystonia</i>
Sustained muscle contraction that leads to repetitive twisting movements of variable speed and abnormal posture
<i>Tremor</i>
Rhythmic, oscillatory movements of a body part
<i>Tic</i>
Intermittent, repetitive, stereotypical, abrupt, jerky, typically affecting the face and head
<i>Stereotypy</i>
Purposeless, uniformly repetitive, voluntary, movement of whole body areas
<i>Akathisia</i>
Subjective restlessness, compulsion to move about
<i>Myoclonus</i>
Sudden, brief, irregular, contraction of a group of muscles

movement disorders are often managed identically (with the exception of medication-induced movement disorders).

### The Parkinson's Plus Syndromes

The Parkinson's plus syndromes include multiple system atrophy (MSA), progressive supranuclear palsy (PSP), and diffuse Lewy Body disease (DLBD). In the first 1 to 2 years of illness, these disorders may mimic Parkinson's. It is only with careful clinical follow-up and monitoring of an individual's response, or lack of a response, to dopamine replacement, that a reasonable clinical diagnosis can be made.

MSA is characterized by urinary incontinence, reduced sweating, and orthostatic hypotension (122). In someone with MSA, these symptoms occur within the first 3 to 5 years of disease onset. In someone with Parkinson's disease, these symptoms may occur, but only 10 to 15 years after disease onset. Clinically, those with MSA do not improve with dopamine replacement.

PSP is characterized by the inability to exercise voluntary movement of the eyes (123). Another feature of PSP is a marked change in personality; affected individuals become apathetic and may appear to be depressed. In addition, PSP causes marked gait difficulty and those affected tend to have frequent falls within 1 or 2 years after developing symptoms. Thus, gait abnormalities become evident more rapidly in those with PSP than in those with Parkinson's disease.

DLBD is characterized by a marked decline in intellectual function, visual hallucinations, and signs of bradykinesia, rigidity, and possibly rest tremor (124). In DLBD, the

dementia and visual hallucinations progress rapidly within the first 3 years of symptom onset. The bradykinesia and rigidity progress more slowly. Unfortunately, treatment is limited because dopamine replacement, which would alleviate the motor symptoms of bradykinesia and rigidity, worsen the visual hallucinations and can produce an acute worsening of the underlying dementia.

One feature common to all the Parkinson's plus syndromes is that the symptoms do not improve with dopamine replacement. This is in stark contrast to Parkinson's, in which the symptoms do improve significantly with dopamine replacement. It is this lack of response to dopamine, as well as the monitoring of the progression of symptoms, that help to distinguish these syndromes from Parkinson's and from one another.

### Tremors

Tremors are regular, oscillatory movements produced by alternating but synchronous contractions of antagonistic muscles (125–127). Their rhythmic quality distinguishes them from other involuntary movement disorders (128,129). Clinically, tremors are classified as resting, essential, or action. A resting tremor occurs when the affected limb is at rest and the muscles are relaxed. Resting tremors are typically seen in those with Parkinson's or one of the Parkinson's plus syndromes. An essential tremor is a visible and persistent tremor that occurs when the arms or head is in a specific position or when they move. Most cases of essential tremor are hereditary and are ameliorated with alcohol, benzodiazepines, propranolol, or primidone. The action tremor is one that exists with any voluntary muscle contraction. Specifically, an "intention tremor" is a subtype of action tremor, in that the type of muscle contraction is kinetic as opposed to isometric or postural (130).

### Dystonia

Dystonia refers to a sustained muscle contraction that causes repetitive, twisting movements of variable speed, leading to abnormal posture. Dystonia may be focal, segmental, multifocal, or generalized (131–134). Focal dystonia involves single body parts (e.g., blepharospasm, "writer's cramp"), whereas the segmental variety affects two or more contiguous regions (e.g., craniocervical). Multifocal dystonia consists of abnormalities in noncontiguous body parts. Generalized dystonia involves segmental crural dystonia and at least one other body part. Unilateral dystonia is also called hemidystonia.

Regardless of anatomic distribution, dystonic contractions typically begin intermittently and become severe and persistent, leading to sustained abnormal postures. Secondary dystonia is associated with neurologic disorders, such as brain injury, cerebral tumor, and infections (135–137). (Secondary dystonias may also be caused by medications, such as phenothiazines and sertraline [138].)

Impairment of basal ganglia output is thought to play a role in the genesis of dystonia (139). In a series of 22 subjects with hemidystonia, 73% had prior hemiparesis or basal gan-

glia lesions on imaging studies (140). Lesions in the putamen have been linked to hemidystonia, whereas bilateral putaminal involvement may be responsible for generalized dystonia (131). Torticollis and hand dystonia are thought to result from involvement of the head of the caudate nucleus and thalamus, respectively (140). Disease of the thalamus and subthalamus and derangement of hypothalamic function have also been suspected (141,142).

The current lack of understanding of the exact pathophysiology of dystonia has made it difficult to define specific pharmacological therapy. Treatment has become a "trial-and-error" process, often leading to frustration for the patient and clinician (132,133,143). Oral medications used to treat the various dystonias include dopamine agonists, antagonists, and depletors; anticholinergics; benzodiazepines and baclofen (GABA<sub>A</sub> and GABA<sub>B</sub> agonists, respectively). Unfortunately, these systemic medications have numerous adverse effects. Local injection of botulinum toxin is a safe and efficacious alternative, particularly for focal dystonias. The efficacy of physical therapy techniques, such as soft-tissue mobilization, cervical muscle strengthening and stretching, and orthotic intervention have not been well studied to date. Similarly, limited success has been achieved through behavioral modifications, including hypnosis, biofeedback, and relaxation techniques.

### Cervical Dystonia

Cervical dystonia, the most common focal dystonia, involves the sternocleidomastoid, trapezius, and posterior cervical muscles. It gives rise to patterned, repetitive, and spasmodic movement that causes the head to twist (rotational torticollis), extend (retrocollis), flex (anterocollis), or tilt toward the shoulder (laterocollis). One or more of these head movements may occur simultaneously. Walking or standing worsens the condition, but the patient may be able to return the head to midline by placing the hand on the jaw or chin. The neck movement may be associated with blepharospasm, lip or chewing movements, and tremor.

Because they play a role in maintaining normal head posture, the basal ganglia and the vestibuloocular reflex pathway have been implicated in the development of cervical dystonia (144–147). Disturbances of neurotransmitter systems have also been described in dystonias (148). Abnormalities in blink reflex recovery have suggested involvement of the brain stem (149). Earlier cervical and upper-limb trauma have also been implicated in development of cervical dystonia (150–152).

With respect to treatment, baclofen, benzodiazepines (e.g., clonazepam), anticholinergics (e.g., trihexyphenidyl), carbamazepine, and dopamine agonists or antagonists have been trialed, but side effects may limit their use. Local injection of botulinum toxin into the offending muscles (i.e., sternocleidomastoid, trapezius, splenius capitis) has been successful and not associated with significant complications. In few cases, dysphagia may develop due to local spread of the toxin to neighboring pharyngeal and laryngeal muscles.

### Chorea, Athetosis, and Ballismus

Chorea, derived from the Greek word for dance, is an involuntary movement that is brief, rapid, forceful, and dysrhythmic (153). In general, choreic movements are discrete and purposeless and involve distal body regions such as the hands and feet. Athetosis refers to writhing, snakelike involuntary movements that involve larger and more proximal muscle groups, such as the entire arm or leg. It is believed that the contralateral STN, caudate nucleus, and putamen may be responsible for chorea (154–157). Bilateral thalamic involvement has been described as well. Choreic movements have been evident in Sydenham's chorea, hyperthyroidism, cerebral arteritis, polycythemia vera, systemic lupus erythematosus, Huntington's disease, and phenothiazine intake (137,158).

The movements in athetosis are typically slower than choreiform movements. They are characterized by writhing movements and the inability to maintain the position of virtually any body part (e.g., fingers, wrists, toes). Although the limbs are most commonly affected, the axial musculature may be involved as well. Athetoid movements may be seen in Wilson's disease, cerebral palsy, and basal ganglia disease. In some cases, athetosis is drug induced. When it appears with chorea, it is referred to as *choreoathetosis*.

In contrast to chorea, movements related to ballismus are of large amplitude and involve the proximal limbs. The movements often come on suddenly, with no clear pattern. Because ballismus is frequently unilateral, it is also commonly referred to as *hemiballismus*. Involvement of the contralateral STN has been suggested, but other subcortical structures may also be involved (155–157,159,160). It is thought that a lesion in the contralateral STN disrupts the inhibitory pathways to the globus pallidus, leading to dopamine hyperactivity in the striatum (161). Bilateral involvement (biballism) is seen in bilateral basal ganglia disease (162). Ballismus has also been associated with metabolic abnormalities, such as hyperglycemia, neoplasms, systemic lupus erythematosus, and encephalitis (156,163).

Antiepileptic drugs, such as phenobarbital and valproic acid, may be of benefit in chorea, athetosis, and hemiballismus. In hemiballismus, dopamine antagonists, such as haloperidol and phenothiazines, and dopamine-depleting agents, such as reserpine and tetrabenazine, may be helpful (160). GABA agonists, such as clonazepam, may also ameliorate chorea in that GABA appears to mediate the inhibitory action of the STN (160). Stereotactic thalamotomy may be considered in severe conditions refractory to medications (164).

### Tics, Stereotypy, and Akathisia

Tics are intermittent, stereotypical, repetitive, jerky movements. Although the individual is aware of such movements, he or she finds it difficult to resist performing the action (165). Tics can be either motor or vocal. Many tics are associated with purposeful tasks such as eye blinking and throat clearing. They generally do not interfere with willed, voluntary movements and may be volitionally suppressed to some extent. Tics may also be classified as simple, such as grimacing, or complex, as in

the many tics characteristic of Gilles de la Tourette syndrome (166). In general, tics disappear during sleep and worsen during stressful situations.

Stereotypy is purposeless, uniformly repetitive, voluntary movement of whole body areas. Examples include head nodding, head banging, body rocking, and arm jerking, seen in individuals with mental retardation and amphetamine addiction (141).

Akathisia is formally defined as inner restlessness and compulsion to move about. Although a subjective experience by definition, it may manifest overtly as the inability to stand or sit still, or as an urge to pace constantly. In some, the only finding is toe tapping or leg shaking. Akathisia is often seen in the early stages after traumatic brain injury, when it is often difficult to distinguish from other behavioral sequelae, such as agitation. Akathisia is thought to result from dopamine blockade in the frontal area (167). Thus, antidopaminergic medications, such as neuroleptics, may also induce this disorder. Dopamine agonists, such as ropinirole, are sometimes used. Clomipramine, clonidine, propranolol, piracetam, and clozapine (168,169) may also be beneficial. Neuroleptic-induced akathisia may be treated with amantadine, but it is best managed by reducing the dose or discontinuing the offending drug (170).

### Psychogenic Movement Disorders

Psychogenic movement disorders result from various psychiatric conditions, and up to 9% of conditions presenting with neurological symptoms are believed to have no "organic" basis (171,172). A recent evaluation of self-reporting of disability in patients with psychogenic movement disorders versus those with Parkinson's revealed that the severity of perceived disability was equivalent in both populations (173). In a retrospective evaluation of 4,470 patients, 405 (about 9%) were found to have psychogenic disorders, with motor disorders as one of the more common symptoms (171). In a series of 842 patients with movement disorders, 3.3% were diagnosed as having clinically documented psychogenic movement disorders (172).

Common psychogenic movement disorders are tremor, dystonia, myoclonus, tics, chorea, hemiballismus, and parkinsonism (174). One feature suggestive of psychogenic movement disorders is an inconsistent or fluctuating clinical presentation of symptoms. Psychogenic movement disorders also usually have an acute onset and static course characterized by spontaneous remissions. They are worsened by attention and dampened by distraction. Typically, they are no more responsive to medications than placebo.

When psychogenic movement disorders are entertained, attempts should be made to make a psychiatric diagnosis even if the diagnoses of psychogenic movement disorders are based on neurological examination. Common psychiatric diagnoses include conversion, malingering, somatoform disorder, factitious disorder, depression, and anxiety. Associated psychiatric diagnosis (usually depression), precipitating events, and secondary gain are obvious in up to 60% of cases of psychogenic movement disorders. Behavioral management, encouragement

and support, in addition to rehabilitation, have shown some efficacy in managing psychogenic gait disorders; however, when symptoms are present  $\leq 12$  months, there is high likelihood for long-term disability (175).

### Drug-Induced Movement Disorders

Medications are common causes of movement disorders and should be considered in the evaluation of movement disorders (176). Neuroleptics are among the most common of the medications that can directly trigger movement disorders. Extrapyramidal syndromes, including akathisia, parkinsonism, dystonia, and tardive dyskinesia, represent untoward motor side effects of antipsychotic drug therapy. The mechanism is thought to involve postsynaptic blockade of dopamine receptors (169,177,178).

Acute extrapyramidal syndromes present within a few days following administration of neuroleptics and may persist days after withdrawal of the offending agent. Although considered different manifestations of the same underlying etiology, drug-induced akathisia, dystonia, and parkinsonism have unique motor and mental symptoms that help distinguish one from another (178). A less common extrapyramidal reaction to neuroleptics is acute laryngeal dystonia (176).

Tardive dyskinesia, characterized by orofacial dyskinesia, dystonia, and choreoathetosis, is thought to result from hypersensitivity of dopamine receptors in the basal ganglia (due to prolonged postsynaptic receptor blockade by neuroleptics). Advanced age, female gender, history of alcohol or substance abuse, diabetes, and smoking are considered risk factors for tardive dyskinesia in older individuals (177). In contrast to tardive dyskinesia, the parkinsonian side effect is thought to arise from blockade of dopamine receptors in the striatum.

Other drugs have been implicated in the development of movement disorders. For instance, lithium, methyl dopa, and metoclopramide may bring about parkinsonism (179). Choreoathetosis may result from tricyclic antidepressants, oral contraceptives, amphetamines, pemoline, and lithium (180). Diphenhydramine and flecainide have been reported to cause dystonia, asterixis has been associated with carbamazepine, and phenytoin has been implicated in the development of choreoathetosis (181,182,183,184). Table 26-9 lists drugs commonly encountered in psychiatric and neurological practice that may induce movement disorders (185–189).

## OTHER TREATMENT CONSIDERATIONS

### Botulinum Toxin Injection

Local intramuscular injection of botulinum toxin is arguably the most important advance in the nonsurgical management of dystonia and other movement disorders. The clinically available neurotoxins, derived from *Clostridium botulinum* serotypes A and B, block neuromuscular transmission by inhibiting the release of acetylcholine (but not its synthesis or storage). Injected intramuscularly, the toxin results in partial denervation. Clinical effects are seen 24 to 72 hours after injection,

**TABLE 26.9** Some Medications That May Induce Movement Disorders

Dopamine antagonists
Haloperidol
Metoclopramide
Dopamine agonists
Levodopa
Antihypertensives
Methyldopa
Monoamine oxidase inhibitors
Antiepileptics
Phenytoin
Carbamazepine
Valproic acid

Buspirone
Lithium
Cimetidine
Oral contraceptives
Cocaine
Selective serotonin reuptake inhibitors

Adapted from Jain SS, Francisco GE. Parkinson's disease and other movement disorders. In: DeLisa JA, ed. *Rehabilitation Medicine: Principles and Practice*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1998:1035–1041.

and peak effects occur 4 to 6 weeks later. The average duration of effect is 3 to 4 months. Injections are guided by surface anatomy, electromyography, or electrical stimulation.

Early indications for treatment were blepharospasm and strabismus. Over the years, further disorders have been found to be successfully managed by the technique. Among these are the various dystonias: cervical dystonia (spasmodic torticollis), hemifacial spasm, orolingual dystonia, cranial dystonia, limb dystonia, and “occupational cramps” (190,192–194).

Physiatrists can employ their knowledge of anatomy, kinesiology, and electromyography when treating with botulinum toxin. Because it affects neuromuscular transmission, the toxin is contraindicated in disorders of neuromuscular junction, such as myasthenia gravis and myasthenic syndrome. However, successful use in the treatment of spasmodic torticollis in a patient with myasthenia gravis has been reported (195). Possible adverse effects include excessive weakness in the injected and adjacent muscles. Flu-like symptoms and allergic reactions have been described, but this has rarely occurred in our experience. The clinical effects wear off after 3 to 4 months, and reinjection may be necessary. Readministration

of the toxin within 3 months of the previous injection is discouraged to avoid potential development of antibodies.

### Intrathecal Baclofen

Intrathecal baclofen is helpful in alleviating focal limb and axial dystonia (196,197). Recently, we successfully treated a man with posttraumatic hemiballismus, and dystonia was successfully treated with intrathecal baclofen. After intrathecal infusion of baclofen, there was a dramatic decrease in the frequency and amplitude of ballismus. Although early reports suggest that intrathecal baclofen may be helpful, its efficacy has not been supported by controlled trials. Furthermore, outcomes from intrathecal baclofen therapy have not been compared directly with those from oral medications, botulinum toxin, and other neurosurgical techniques.

This procedure is an alternative when oral medications are ineffective and their side effects are intolerable, or when the severity of the condition requires more than the recommended dose of botulinum toxin. Although these injections are a neurosurgical procedure, physiatrists may participate in screening patients with movement disorders who might benefit from intrathecal baclofen. Trained physiatrists also play a critical role in postimplantation rehabilitation care by monitoring response and complications and prescribing appropriate therapy interventions.

Patients who respond to a trial dose of intrathecal baclofen are considered for surgical implantation of the infusion system. The pump, with the drug reservoir, is placed in the abdominal wall and connected to a catheter that has been introduced to the intrathecal space, usually at the lower thoracic level. An external programmer adjusts the dose, rate, and mode of drug delivery by radiotelemetry. The drug reservoir can be refilled through transcutaneous insertion of a Huber-type needle into the reservoir port.

Simple dose titration and safe concurrent use with other therapies, such as oral drugs and botulinum toxin, are among the advantages of intrathecal baclofen. Common adverse effects include drowsiness, weakness, and dizziness, which subside with dose reduction. Pump-related problems include catheter kink, fracture, dislodgment, and disconnection, which are corrected surgically.

# Rehabilitation of Spinal Cord Injury

The earliest reference to spinal cord injury (SCI) is found in the Edwin Smith Surgical Papyrus, written between 2,500 and 3,000 BC, as “an ailment not to be treated” (1). Much has changed in the last 50 years in spinal cord care as it relates to increasing survival, life expectancy, community reintegration, and quality of life (QOL). Major advances include the specialized spinal cord centers of care; model SCI centers funded by the National Institute on Disability and Rehabilitation Research (NIDRR), Department of Education, United States; establishment and growth of organizations and journals dedicated to SCI; and the development of the subspecialty of SCI Medicine in 1998. The subspecialty of SCI medicine addresses the prevention, diagnosis, treatment, and management of traumatic and nontraumatic (NT) etiologies of spinal cord dysfunction (2). Physicians with training in a variety of related specialties are eligible for fellowship training and can become certified after passing a written exam. The advances of the last decade alone have been dramatic in terms of the understanding of the pathology of the initial and secondary aspects of the injury, and the barriers that must be overcome to enhance recovery. Newer techniques to improve function and intervene at the cellular level for possible cure are being developed that will further allow individuals who sustain a SCI to be more independent in the future.

## EPIDEMIOLOGY OF TRAUMATIC SCI

### Incidence and Prevalence

The National SCI Statistical Center (NSCISC) database has been in existence since 1973 and captures approximately 13% of all new traumatic SCI that occur in the United States each year, and has been used to develop an epidemiological profile (3–6). When compared to population-based studies, persons in this database are representative of all SCIs except that more severe injuries, nonwhites, and injuries due to acts of violence are slightly overrepresented. The incidence of traumatic SCI in the United States has remained relatively constant, at approximately 40 new cases per million population, or approximately 12,000 cases per year. The incidence of SCI in the rest of the world is consistently lower than in the United States (7). The prevalence in the United States is estimated at 250,000 persons.

### Age, Gender, and Race

SCI primarily affects young adults, with most injuries occurring between the ages of 16 and 30, but over time the average

age at injury has steadily increased. Approximately 5% of traumatic SCI occur below the age of 15. From 1973 to 1979, the average age at injury was 28.7 years, but since 2000 is 39.5 years, with 11.5% of persons injured older than 60. Reasons for the observed trend toward older age at injury may include changes in the referral patterns to model SCI systems and the location of the systems that contribute data to the NSCISC, survival rates of older persons at the scene of the accident, or age-specific incidence rates. In adults, men suffer traumatic SCI more commonly than women, at a 4:1 ratio. In the pediatric population, the difference is less dramatic (see Chapter 74). State registries and NSCISC data reveal higher incidence rates of SCI for African Americans than Whites, although this trend may have changed in 2000 (4). It is unknown whether changing locations of or referral patterns to model SCI systems, or race-specific incidence rates are responsible for this trend.

### Etiology and Time of Injury

Motor vehicle crashes (MVCs) including automobile, motorcycle, and bicycle, rank first (since 2005, MVCs account for 42% of cases), followed by falls (27.1%), acts of violence (15.3%) (primarily, gunshot wounds [GSW]), and recreational sporting activities (7.4%) (6). MVCs account for a lower percentage of cases among men than women while men have a higher percentage of SCI that are due to GSW, diving mishaps, and motorcycle crashes (4). The likelihood of SCI from a MVC is higher in non-sedan cars (e.g., sport utility vehicles) involved in rollover crashes (8). MVC is the leading cause of traumatic SCI until age 45, when falls become the leading cause. Falls are most often from low heights, resulting in a cervical lesion (9). There is an increased frequency of cervical spinal stenosis, placing the elderly population at a greater risk of SCI with relatively minor trauma.

Acts of violence caused 13.3% of SCI prior to 1980, and peaked between 1990 and 1999 at 24.8%, before declining to 15.3% since 2005 (6). Violence causing SCI is more common in minority groups. Diving injuries account for the majority of SCI due to recreational sports, followed by snow skiing, surfing, wrestling, and football. Recreational sports and acts of violence decrease with advancing age, as a cause of injury.

In children, the incidence of SCI in the United States is 1.99 cases per 100,000. MVCs are the leading cause, and in children involved in a MVC, two thirds are reported as not wearing a seat belt. Alcohol and drugs are reportedly involved

in 30% of all pediatric cases. Boys are twice as likely to have a SCI as girls, with an overall mean age of 14.6 years. Incidence of pediatric SCI varies by region, with the South and Midwest regions having almost twice as many as in the Northeast (10).

Traumatic SCI occurs with greater frequency on weekends, with the greatest incidence on Saturday. Seasonal variation exists, with peak incidence occurring in July followed closely by August and June. The seasonal pattern is more pronounced in the northern part of the United States.

### Associated Injuries

Spinal cord injuries are often accompanied by other significant injuries. The most common include broken bones (i.e., ribs, long bones), loss of consciousness, and traumatic pneumothorax. The nature and frequency of these injuries is, typically, associated with the etiology of the SCI. For example, pneumothorax occurs more frequently with GSW as compared with other causes of SCI. Noncontiguous spinal injuries (a lesion separated by at least one normal intervening vertebra from a spine fracture or subluxation/dislocation) occur in 12% to 28% of cases as documented by magnetic resonance imaging (MRI) (11,12).

### Neurological Level and Extent of Lesion

Traumatic SCI, most commonly, causes cervical lesions (approximately 50%) followed by thoracic and then lumbosacral lesions. The C5 segment is the most common lesion level, followed by C4, C6, T12, C7, and L1, as per documentation at the time of discharge from inpatient rehabilitation programs (7). Since 2000, the most frequent neurologic category at discharge from rehabilitation of persons reported to the NSCISC database is incomplete tetraplegia (34%), followed by complete paraplegia (23%), incomplete paraplegia (18.5%), and complete tetraplegia (18.3%) (6). Pediatric SCI more often results in paraplegia and neurologically complete injuries than adult SCI. Less than 1% of persons experience complete neurologic recovery at discharge. The percentage of persons with incomplete tetraplegia has recently increased, while that of those with complete paraplegia and tetraplegia has decreased slightly.

The etiology of injury is strongly associated with the level and severity of the injury. Most recreational sports-related injuries, falls, and approximately 50% of MVC result in tetraplegia, whereas acts of violence usually result in paraplegia (4,7). Neurologically complete injuries are more likely to occur as a result of acts of violence and among younger age groups. Thoracic injuries are most likely to be neurologically complete while most lower level lesions are incomplete injuries. Cervical injuries are most commonly classified as either ASIA Impairment Scale (AIS) A or D.

### Marital and Occupational Status after SCI

Considering the relatively youthful age of most persons with SCI, it is not surprising that most (52.5%) are single when injured. Divorce is increased as compared to the general population among those who were married at the time of injury,

especially in the first 3 years after injury, as well as those who marry after injury. The likelihood of getting married after injury is also reduced (6,13,14).

More than half (57.4%) the persons with SCI, admitted to a model system, reported being employed at the time of their injury (6). Approximately 25% of persons with SCI are employed postinjury, but the percentage varies substantially by neurologic level and extent of injury (15,16). The higher the level and the more severe the injury, the less the chance of returning to gainful employment. By postinjury year 10, 32% of persons with paraplegia and 24% of those with tetraplegia are employed (6). Most have full-time rather than part-time jobs. Predictors of returning to work include greater formal education, being of younger age (with employment rates declining particularly after age 50), male, Caucasian, married, employed at the time of injury, AIS D injury, having greater motivation to return to work, nonviolent SCI etiology, able to drive, lower level of social security disability benefits, calendar year after the passage of the Americans with Disabilities Act, and a greater elapsed time postinjury (15,16). Persons who return to work within the first year of injury usually return to the same job and employer, while those who return to work after 1 year usually acquire a different job with a different employer, often after retraining. Professional/technical and clerical/sales jobs are the most common.

### Discharge Placement

Approximately 88% of persons discharged from a model system are discharged to a private residence within the community (in most cases their homes before injury), with 5.6% being discharged to a nursing home (NH) (6). The remaining patients are discharged to hospitals, group living situations, or other destinations. Predictors of NH placement include being ventilator-dependent, older in age, tetraplegia with nonuseful motor recovery, unmarried, unemployed, and having either Medicaid or health maintenance organization insurance (17). There has been a significant trend toward an increasing percentage of persons being discharged to NH since 1995 with the advent of shorter inpatient rehabilitation lengths of stay (LOS) (17,18).

Average days hospitalized in the acute care unit for those who enter a model system immediately following injury has declined from 25 days in 1974 to 15 days in 2005. Similar downward trends are noted for days in the rehabilitation unit (from 115 to 39 days). Overall, mean days hospitalized (during acute care and rehabilitation) are greater for persons with neurologically complete injuries (6).

### Life Expectancy

Mortality rates are significantly higher during the first year after injury than during subsequent years, particularly for severely injured persons. Life expectancy of persons with SCI has improved significantly from 50 years ago, but remains below normal. Over the last three decades, there has been a 40% decline in mortality during the first 2 years after injury. While overall life expectancy has improved, the decline in mortality over time in the post 2-year period is small (19). Predictors of mortality after injury include male gender, advanced age,

**TABLE 27.1** Life Expectancy (Years) for Post-Injury by Severity of Injury and Age at Injury (for Persons Surviving At Least 1 Year Post-Injury)

Age at Injury	No SCI	Motor Functional at Any Level	Para	Low Tetra (C5-8)	High Tetra (C1-4)	Ventilator-Dependent at Any Level
20	58.4	53.0	45.8	41.0	37.4	23.8
40	39.5	34.5	28.2	24.2	21.2	11.4
60	22.2	18.0	13.2	10.4	8.6	3.2

Source: National Spinal Cord Injury Statistical Center. Facts and figures. *J Spinal Cord Med.* 2008;31:119–120.

ventilator dependence, injured by an act of violence, high injury level (particularly C4 or above), a neurologically complete injury, poor self-rated adjustment to disability, poor community integration, poor economic status indicators, and having either Medicare or Medicaid third-party sponsorship of care (19–21).

Life expectancy estimates (Table 27-1) are typically based on neurological level of injury (NLI), degree of injury completeness, age at injury, and ventilator dependency (6). For persons with complete injuries, mortality rates are higher for those with high tetraplegia (C1-3) than for those with mid or low tetraplegia, and the latter have higher mortality than those with paraplegia. The distinction between injury grades is more important for those with the highest levels of injury, but not for those with lower injuries. For persons with paraplegia, there is no significant difference between AIS grades of A, B, or C injuries. Those with higher paraplegia (T1-6) have a higher mortality than lower injuries (18).

### Causes of Death

Diseases of the respiratory system are the leading cause of death following SCI, with pneumonia being the most common. Heart disease ranks second, followed by septicemia (usually associated with pressure ulcers [PUs], urinary tract or respiratory infections), and cancer (6,7,20–22). The most common location of cancer is the lung, followed by bladder, prostate, and colon/rectum.

Pneumonia is by far the leading cause of death for persons with tetraplegia while heart disease, septicemia, and suicide are more common among persons with paraplegia. The suicide rate is highest in younger patients and in persons with paraplegia (20,22). Among persons with incomplete motor-functional (American Spinal Injury Association [ASIA] D) injuries at any neurologic level, heart disease ranks as the leading cause of death (24%), followed by pneumonia (11%). Heart disease is the primary cause of death in persons injured for more than 30 years and in patients over 60. While genitourinary (GU) disease (i.e., renal failure) was the leading cause of death 30 years ago, this has declined dramatically, most likely due to advances in urological management.

### Lifetime Costs

Data are available from the model systems for the direct costs of the SCI, with the indirect costs (i.e., lost wages, fringe

benefits) not included in these estimates (6). Estimates from a 1998 publication of the total annual costs of SCI were \$9.73 billion (23). The average yearly health care and living expenses and the estimated lifetime costs that are directly attributable to SCI vary by the year postinjury (first year versus subsequent years), by the level, and severity of injury (6).

## ACUTE MEDICAL AND SURGICAL MANAGEMENT

Clinical practice guidelines (CPG) have recently been published on the early management of adults with SCI (24). The treatment of a traumatic SCI begins at the scene. An injury to the spinal column should be suspected whenever trauma occurs. As such all trauma victims should have their spine immobilized, preferably with a rigid cervical collar with supportive blocks on a backboard, with straps to secure the entire spine in patients with a potential spinal injury, and should be transferred onto a firm padded surface while maintaining spinal alignment to prevent skin breakdown. Movement should be via logrolling until spinal injury has been ruled out. Traditional cardiopulmonary resuscitation (CPR) methods should be utilized, minimizing trauma to a potentially unstable cervical spine that is utilizing the jaw-thrust maneuver to access the airway. After injury, prompt resuscitation, stabilization of the spine, and avoidance of additional neurologic injury and medical complications are of greatest importance. During the first seconds after SCI, there is release of catecholamines with an initial hypertensive phase. This is rapidly followed by a state of spinal shock, defined as flaccid paralysis and extinction of muscle stretch reflexes below the injury level, although this may not occur in all patients. Ditunno et al. proposed four phases of spinal shock from initial loss of reflex activity to hyperreflexia (25). Neurogenic shock, as part of the spinal shock syndrome, is a direct result of a reduction in sympathetic activity below the level of injury, consists of hypotension, bradycardia, and hypothermia, and is common in the acute postinjury period. Parasympathetic (PS) activity predominates, especially in persons with injuries at or above the T6 level. Treatment of hypotension involves fluid resuscitation (usually 1 to 2 L) to produce adequate urine output of greater than 30 cc/h. In neurogenic shock, further fluid administration must proceed cautiously, as the patient

is at risk for neurogenic pulmonary edema, and vasopressors are utilized. Maintenance of mean arterial pressure at approximately 85 mm Hg during the first week postinjury has been associated with improved neurological outcomes (24,26).

Bradycardia is common in the acute period in cervical spinal level injury and may be treated, if below 40 per minute or if symptomatic, with intravenous (IV) atropine (0.1 to 1 mg), or prevented with atropine given prior to any maneuver that may cause further vagal stimulation (i.e., nasotracheal suctioning). While significant bradycardia typically resolves within 6 weeks, episodes of persistent bradycardia beyond this time may occur in some severe injuries. Some patients may require implantation of a cardiac pacemaker to facilitate safe mobilization (27).

Respiratory assessment is critical for acute SCI patients, and should include arterial blood gases and measurement of forced vital capacity (VC) as an assessment of respiratory muscle strength (28). A VC of less than 1 L indicates ventilatory compromise and the patient usually requires assisted ventilation. Serial assessments should be obtained for those with borderline values. A nasogastric tube should be inserted during the initial assessment period to prevent emesis and potential aspiration. A Foley catheter should be inserted with an acutely for urinary drainage and facilitates accurate assessment of urine output and should be left in place until the patient is hemodynamically stable and strict attention to fluid status is no longer required (24).

Upon presentation to the emergency department, a baseline neurological examination should be performed, maintaining spinal precautions. Imaging studies including x-rays, computed tomography (CT) scan, or MRI should be employed to assess spinal fracture, instability, and/or spinal cord pathology. A standard trauma series includes cross-table laterals and AP views of the cervical and thoracolumbar spine. Because of the incidence of noncontiguous fractures (10% to 40%), once one fracture is identified careful inspection of the rest of the spine is imperative. CT scans often provide improved visualization of the C1 and C7 vertebrae while MRI provides optimal visualization of the neuronal structures. The spine should remain immobilized until an injury has been definitively excluded or the spine is stabilized either surgically or by application of an appropriate orthotic device. In patients with a stiff spine and midline tenderness, the clinician should suspect a fracture (even if plain x-ray is negative), especially in the presence of spondylosis, ankylosing spondylitis, or diffuse interstitial skeletal hyperostosis (DISH) (24). In cases of cervical dislocations (if patient is cooperative), weights can be applied to Gardner-Wells tongs to achieve cervical distraction and spinal realignment. Application of a halo or surgery will follow. Forty-seven percent of patients with spine trauma and 64% of patients with SCI have concomitant injuries, including head, chest, rib, and long bone fractures (29). Therefore, a thorough assessment of the total patient is imperative.

Stab wounds and GSWs generally do not produce spinal instability and therefore usually do not require surgical stabilization or orthotic immobilization. Objects that are embedded

around the spinal canal (i.e., knife) should be left in place with removal performed in the operating room under direct visualization of the spinal canal. Bullets that pass through the abdominal viscera are treated with broad spectrum antibiotics and tetanus prophylaxis (30,31). Bullets do not have to be removed; however, they can be if accessible while performing another surgical procedure.

In many trauma centers in the United States, intravenous (IV) methylprednisolone (MP) is given to adults after an acute SCI. Mechanisms of action for MP include improving blood flow to the spinal cord, preventing lipid peroxidation, free radical scavenger, and having anti-inflammatory function. The National Acute SCI Study (NASCIS) 2 reported that IV MP given within 8 hours of injury (30 mg/kg bolus and 5.4 mg/kg/h for 23 hours) improves neurologic recovery at 6 weeks, 6 months, and 1 year, although functional recovery was not clearly studied (32). NASCIS 3 reported that if initiated within 3 hours of SCI, MP should be continued for 24 hours, whereas if initiated at 3 to 8 hours after SCI it should be continued for 48 hours (33). The administration of MP is not extended beyond 8 hours from SCI or in those with penetrating injuries, as they have shown no benefit and their use is associated with a higher incidence of infections (34,35). The benefits and safety of utilizing the NASCIS protocol has been questioned, due to the fact that the findings have not been consistently replicated, concerns regarding methodology and analysis, as well as possibly increased morbidity and mortality in persons administered steroids (36–38). The neurosurgical guidelines consider the use of high dose MP to be a treatment option rather than a standard (39), and the CPG states that there is no clinical evidence to definitively recommend the use of any neuroprotective pharmacologic agent, including steroids, in the treatment of acute SCI to improve functional recovery (24).

Additional recommendations of the CPG include transferring the SCI patient to a specialized center as soon as possible to decrease complications and hospital LOS. Patients with acute SCI, especially high level tetraplegia, should be assessed for evidence of concomitant traumatic brain injury (TBI) (i.e., assessing for loss of consciousness or post-traumatic amnesia [PTA]). Early stabilizations should be considered for extra-spinal fractures. In cases of high-energy injuries, aortic injury should be evaluated. For anesthesia, avoid the use of succinylcholine after the first 48 hours postinjury (potentially fatal hyperkalemic response). While priapism is frequently seen, it is usually self-limited and does not require treatment. Lastly, it is important to maintain normoglycemia in critically ill, mechanically ventilated patients (24).

Not all SCI is associated with a spinal fracture or dislocation (24) and may result from forced extreme range of spinal movement without mechanical abnormality. A high index of suspicion for SCIWORA (SCI without radiological abnormality) is important when evaluating adolescents with sports-related neck trauma or victims of child abuse (especially in children who may be suffering from physical abuse) (24). See Chapter 59 for pediatric-related SCIWORA.

### *Spinal Stability and Principles of Spinal Stabilization*

White and Panjabi proposed the most widely accepted theory on spinal instability defining it as “the loss of the ability of the spine, under physiologic loads, to maintain its pattern of displacement so that there is no initial or additional neurological deficit, no major deformity, and no incapacitating pain” (40). This definition is applicable at all levels of the axial spine. Radiographic criteria have been established for the diagnosis of clinical instability of the spine. Denis described the widely accepted “three-column theory” for thoracolumbar fractures, where the spine is divided into three columns (Fig. 27-1). The anterior column comprises the anterior vertebral body, the anterior longitudinal ligament and the anterior half of the annulus fibrosus. The middle column consists of the posterior vertebral body, the posterior longitudinal ligament, and the posterior half of the annulus fibrosus. The posterior column includes all the posterior elements (including the pedicles). In this three-column theory of Denis, spinal instability is present if any two of the three columns are violated (41).

Injuries that are primarily ligamentous, such as facet dislocations, are unstable and require internal stabilization procedures (42). The primary goal of surgical intervention in acute SCI is to decompress the neural elements, and either an anterior or a posterior approach may accomplish this. The approach chosen depends on the expertise of the operating surgeon and the specific pathophysiology of the injury. Since the most common etiology of SCI occurs from retropulsion

**FIGURE 27-1.** Denis' three columns for the determination of spinal stability. **A:** the anterior column comprises the anterior longitudinal ligament and the anterior half of the vertebral body. **B:** the middle column comprises the posterior half of the vertebral body and the posterior longitudinal ligament. **C:** the posterior column comprises the pedicles, the facet joints, and the supraspinous ligaments.

of bone and/or disc material from a ventral location into the spinal canal, an anterior approach may be preferable. Anterior surgery, however, is associated with increased complications including recurrent laryngeal nerve lesions leading to speech and swallowing disorders. After adequate neural decompression is accomplished, the spine is stabilized and fused. Fusion is typically performed by using autologous bone which is most frequently harvested from the iliac crest. The fibula can also be used as a donor site for autograft bone; however, this is usually reserved for cases that require more than a single level of fusion. Surgical hardware is utilized to help fixate bones in order to allow a fusion to occur. The hardware, however, is only a temporary fixation device that facilitates the eventual long-term bony fusion. From a posterior approach, techniques include use of interspinous wiring with bone grafting or placement of lateral mass plating with bone grafting.

Postoperatively, or if surgery is not required, an orthosis is usually prescribed, and maintained for approximately 3 months. The type of spinal orthotic chosen depends on the level of spinal injury. Generally, for the occipito-C2 levels the Halo-vest may be used, although some surgeons will utilize a head-cervical orthosis (HCO) (i.e., Miami J Collar (Jerome Medical)). An HCO is utilized for the C3-7 levels; for the T1-3 levels a cervicothoracic orthosis is used (i.e., extended HCO or Yale brace). From T4 through L2, a thoracolumbar spinal orthotic (TLSO) is utilized, however at L3 and below a lumbosacral orthotic (LSO) with the incorporation of one hip/thigh (spica attachment to a LSO or TLSO) will ensure satisfactory immobilization of the low lumbar and sacral spine is required.

### *Specific Injuries to the Spine*

Fractures of the atlas are commonly referred to as “Jefferson” burst fractures. These are usually stable injuries (i.e., may occur after a football spearing injury) that may be treated with a Halo-vest orthosis. Unstable Jefferson fractures usually require posterior surgical stabilization. Odontoid fractures are classified into three basic types. Type I odontoid fractures are very rare and involve a fracture of the tip of the odontoid process. Type II odontoid fractures are much more common, particularly in the elderly population, and involve a fracture through the base of the odontoid process, at its junction with the C2 vertebral body. Type III fractures extend from the base of the odontoid into the body of the C2 vertebra proper. Type I odontoid fractures typically require no specific surgical intervention. Type III odontoid fractures are typically treated with an external orthosis (either Halo-vest or HCO) for 3 months. Type II odontoid fractures may be treated with an external halo/vest orthosis, however, there is a high failure rate with this treatment and internal stabilization may be needed.

Fractures of the pedicles of C2 are usually bilateral and are commonly referred to as “hangman’s” fractures. These can occur during an abrupt deceleration injury, that is, a MVC with the person’s head hitting the windshield, and are most often stable injuries treated with external orthoses. When disruption is more significant, treatment with a halo in slight extension

is utilized. In the case of an unstable hangman's fracture, open surgical fusion may be necessary.

Pure bony injuries in the subaxial spine (C3-7) without substantial neurologic compression may heal with an external orthosis alone. However, most cases of an acute SCI secondary to cervical fractures will have ligamentous injuries and will require open surgical intervention to decompress and/or fuse the cervical spine. The most common burst fracture in the cervical spine occurs at the C5 vertebral level.

The most common thoracic spinal injury involves fracture of the T12 vertebra. Unstable injuries are treated with stabilization and fusion procedures. In the lower thoracic spine, either an anterior or posterior approach may be utilized. Anterior surgery is, typically, performed via a thoracotomy, or a thoracoabdominal approach, when a corpectomy is performed. This is followed by bone grafting and stabilization with either a screw/plate or a screw/rod construct. Anterior surgery in the upper thoracic spine is difficult technically and is rarely performed. Posterior thoracic surgery will classically involve the use of a hook/rod stabilization construct. Stable fractures can be treated with an orthosis (i.e., custom-molded TLSO).

A Chance fracture involves a horizontal splitting of the vertebra extending from posterior to anterior through the spinous process, pedicles, and vertebral body. Despite the extent of vertebral damage, these fractures tend to be stable. They most commonly occur at the thoracolumbar spine (T12, L1, or L2 level). Chance fractures usually result from an acute hyperflexion of the back and were known as "seat-belt" fractures with the advent of lap seat belts in cars. A head-on collision would cause the passenger wearing a lap-belt to suddenly be flexed at the waist, creating stress on the posterior elements of the vertebra. With the combination of shoulder and lap belts, most Chance fractures seen today result from falls or crush-type injuries where the thorax is acutely hyperflexed.

In the lumbar spine, L1 burst fractures are most common. These frequently result from a fall from a height and will result in an injury partially affecting the conus medullaris and/or the cauda equina (CE). Anterior surgery in the lower lumbar spine is difficult due to the presence of the iliopsoas muscles and the great vessels, and as such, below the level of L3 is rarely performed.

The role and timing of spinal surgery including decompression has not been fully clarified in patients with SCI. Early spinal decompression within 24 hours, and perhaps within 8 hours, may improve neurological recovery, particularly in patients with incomplete injuries (24,43). Most previous studies have failed to demonstrate significant neurologic recovery with early surgery (<72 hours) among patients with complete or incomplete lesions (44,45). Preliminary results of the STASCIS (Surgical Treatment of Acute SCI Study) trial showed that 25% of patients who received decompressive surgery within 24 hours of their injury experienced a 2-grade or greater improvement on the ASIA scale, compared with 4% of those in the delayed-treatment (>24 hours) group (46). Further study is needed regarding the timing of surgery and neurological recovery. Data have shown that early surgery reduces LOS

in the acute hospital, facilitates rehabilitation, decreases hospital costs, and reduces postoperative complications (47–49). The current indication for emergent surgical treatment is progressive neurologic deterioration.

## ANATOMY, NEUROANATOMY, AND VASCULAR SUPPLY

The vertebral column is composed of 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal vertebrae. The spinal cord is protected within the vertebral foramen, and initially occupies the entire length of the vertebral canal. By adulthood, the spinal cord occupies only the upper two thirds of the vertebral column with its caudal end located at the lower border of the first lumbar (L1) vertebra (level of L1-2 intervertebral disc) (Fig. 27-2). The spinal cord segments, especially in the thoracic and lumbar regions, do not line up with their corresponding vertebral level, and explains why a fracture of T12 for instance results in a L1-2 NLI. At the caudal end, the spinal cord is conical in shape and is known as the conus medullaris. The lumbar and sacral nerve roots descend some distance within the vertebral canal in order to exit from their respective intervertebral foramina. These nerve roots resemble a horse's tail, and are termed the cauda equina (CE). The lumbar cistern extends from the caudal end of the spinal cord (L2 vertebra) to the second sacral vertebra. The subarachnoid space is widest at this site and is therefore most suitable for the withdrawal of cerebrospinal

*The spinal cord ends between L-1 and L-2. The nerves continue to descend in the spinal column, exiting between the vertebrae and through the sacrum.*

**FIGURE 27-2.** Spinal vertebrae and nerve roots.

fluid (CSF) by lumbar puncture, usually performed between the L3 and L4 lumbar vertebrae.

Thirty-one pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal pair) emerge from the spinal cord. At and below the thoracic level, the nerve roots exit just caudal to the corresponding vertebra while in the cervical region the nerve roots exit through the intervertebral foramina just rostral to the corresponding vertebra. This is due to the fact that there are eight cervical nerve roots and only seven cervical vertebrae; the C8 nerve root exits through the intervertebral foramen just rostral to the first thoracic vertebra.

The spinal cord has two enlargements: cervical and lumbar. The cervical enlargement includes the C5-T1 nerve roots to form the brachial plexus which innervates the upper extremities (UEs). The lumbar plexus (roots L<sub>1</sub> to L<sub>4</sub>) and lumbosacral plexus (L<sub>4</sub> to S<sub>2</sub>) emerge from the lumbar enlargement and innervate the lower extremities (LEs). The sacral spinal nerves emerge from the conus medullaris and contain PS and somatic motor fibers innervating the muscles of the bladder wall and external sphincter, respectively.

The spinal cord receives its blood supply from one anterior and two posterior spinal arteries (PSAs) as well as anterior and posterior radicular arteries. The anterior spinal artery (ASA) arises in the upper cervical region and is formed by the union of two branches of the vertebral arteries. The ASA supplies the anterior two thirds of the spinal cord including the gray matter and anterior and anterolateral white matter. The ASA varies in diameter according to its proximity to a major radicular artery. It usually is narrowest in the T4-8 region of the spinal cord. There are two PSAs that originate from the vertebral artery. The PSAs supply the posterior one third of the spinal cord consisting of posterolateral and posterior white matter of the spinal cord.

The blood supply from the anterior and posterior arteries is sufficient for the upper cervical segments. Segmental arteries that arise from the aorta supply the ASA and PSAs in the thoracic and lumbar regions. The radicular arteries arise from the vertebral, cervical, intercostal, lumbar, and sacral arteries and supply the remaining segments of the spinal cord. The major radicular artery that supplies the lumbosacral enlargement of the spinal cord is known as the artery of Adamkiewicz. It usually arises from the left intercostal or lumbar artery at the level of T6-L3 and provides the main blood supply to the lower two thirds of the spinal cord. There are less radicular arteries that supply the midthoracic region of the spinal cord and are smaller in diameter and therefore create a “watershed zone” of the spinal cord at this level. With clinical situations where there is low blood flow to the spinal cord (i.e., clamping of the aorta for surgery above the renal artery), this level of the cord is most affected (T4-6 level).

The internal structure of the spinal cord is such that a transverse section of the spinal cord reveals a butterfly-shaped central gray matter surrounded by white matter. The gray matter of the spinal cord contains cell bodies and primarily neurons, dendrites, and myelinated and unmyelinated axons. Autonomic neurons are located laterally and exit by the ventral

root and innervate smooth muscle. Lower motor neurons (LMN) are located ventrally, exit by the ventral roots and innervate striated muscle. The white matter consists of ascending and descending bundles of myelinated and unmyelinated axons (tracts or fasciculi). The ascending pathways relay sensory information to the brain while the descending pathways relay motor information from the brain.

Sensory tracts or ascending pathways are composed of axons from peripheral sensory nerves whose cell bodies are located in the dorsal root ganglion (DRG) and ascend toward the brainstem. Receptors for pain and temperature enter the spinal cord and synapse in the dorsal horn of the gray matter. The fibers cross over within one to two vertebral segments, then travel in the lateral spinothalamic tract and ascend to the ventral posterolateral (VPL) nucleus of the thalamus. The fibers then ascend in the internal capsule to reach the postcentral gyrus, which is the primary somatic sensory area of the brain. Pressure and light touch (LT) fibers enter the cord in the same fashion, and pass into the ipsilateral dorsal white column and bifurcate. One branch immediately enters the dorsal horn gray matter, synapses, and crosses over within one to two segments, while the other branch remains ipsilateral, and ascends in the dorsal column for as many as ten spinal segments. The ipsilateral branch ultimately enters the dorsal horn, synapses, and crosses over to join the other branch in the ventral white column, forming the ventral spinothalamic tract. These axons travel in the same pathway as the lateral tract to reach the postcentral gyrus, which interprets these sensations.

The posterior columns transmit three different sensations; proprioception, fine touch, and vibration sense. Their nerve fibers reach the DRG and immediately pass into the ipsilateral dorsal white columns and ascend to the medulla. Axons that enter the cord at the sacral, lumbar, and lower thoracic levels are situated in the medial part of the dorsal column (i.e., the lower part of the body) called the fasciculus gracilis. Those axons that enter at the thoracic (above T6) and cervical levels are situated in the lateral part of the column (from the upper part of the body) and are termed the fasciculus cuneatus. Axons of each fasciculus synapse in the medulla and form a bundle termed the medial lemniscus, which ascends to the postcentral gyrus.

The cerebellum is the control center for the coordination of voluntary muscle activity, equilibrium, and muscle tone. The spinocerebellar tract is a set of axonal fibers originating in the spinal cord and terminating in the ipsilateral cerebellum that conveys information to the cerebellum about limb and joint positions (proprioception).

The lateral corticospinal tract is the main tract for voluntary muscle activity. Its origin is the precentral gyrus of the frontal lobe of the brain. Their axons descend through the internal capsule to the medulla oblongata. Approximately 80% to 90% of the axons cross at the pyramidal decussation to the contralateral side of the medulla and descend in the lateral white columns of the spinal cord, in the lateral corticospinal tract. At each level of the spinal cord, the axons from the lateral tract peel off and enter the gray matter of the

ventral horn and synapse with secondary neurons. The 10% to 20% of uncrossed axons that continue down on the same side of the cord travel in the ventral corticospinal tract. The axons of the ventral tract then cross over at the corresponding level of muscles that it innervates. Both tracts travel from the precentral gyrus to the ventral horn as a single uninterrupted neuron and are termed upper motor neurons (UMN), while the secondary neurons that they synapse on, are termed lower motor neurons.

## NEUROLOGICAL ASSESSMENT

The most accurate way to document impairment in a person with a SCI is by performing a standardized neurological examination, as endorsed by the International Standards for Neurological Classification of SCI Patients (50). These standards provide basic definitions of the most common terms used by clinicians in the assessment of SCI and describe the neurological examination. Key terms are defined in Table 27-2. The examination is composed of sensory and motor components, and is performed with the patient in the supine position to be able to compare initial and follow-up exams. The information from this examination is recorded on a standardized flow sheet

(Fig. 27-3) and helps determine the sensory, motor, and NLI, sensory and motor index scores, and to classify the impairment. An online course for examination and classification utilizing the Standards is available through the ASIA website ([www.asia-spinalinjury.org](http://www.asia-spinalinjury.org)).

**Sensory exam:** The sensory exam is performed separately for LT and pin prick (PP) modalities. Each of 28 dermatomes (Fig. 27-1) is tested and graded 0 for absent, 1 for impaired, 2 for normal (or intact), or NT for not testable. The face is used as the reference point for testing sensation in each dermatome. A grade of 2 indicates the sensation is equal to that of the face. For the pin exam, a grade of 1 indicates the ability to distinguish sharp from dull; however, the sensation is qualitatively different as compared to the face (i.e., either less sharp or hyperesthetic). If the patient cannot distinguish the sharp from the dull aspect of the safety pin used for testing, then the score is 0. In questionable cases, eight out of ten correct answers are suggested as a standard for accuracy. A score of 0 is also given if there is no sensation. For the LT exam, a cotton tip applicator is used. A score of 1 is recorded if the sensation is less than on the face and a 0 if there is no sensation at all. The lowest sacral segment, S4-5 (anal musculocutaneous junction), should be tested with the pin and cotton swab as well. It is important to document the modality of sensation spared, as preservation

**TABLE 27.2** Glossary of Key Terms

**Key muscle group:** Ten muscle groups that are tested as part of the standardized spinal cord examination.

Root Level	Muscle Group	Root Level	Muscle Group
C5	Elbow flexors	L2	Hip flexors
C6	Wrist extensors	L3	Knee extensors
C7	Elbow extensors	L4	Ankle dorsiflexors
C8	Long finger flexors	L5	Long toe extensors
T1	Small finger abductors	S1	Ankle plantarflexors

**Motor level:** The most caudal key muscle group that is graded 3/5 or greater with the segments cephalad graded normal (5/5) strength.

**Motor index score:** Calculated by adding the muscle scores of each key muscle group; a total score of 100 is possible.

**Sensory level:** The most caudal dermatome to have normal sensation for both PP/dull and LT on both sides.

**Sensory index score:** Calculated by adding the scores for each dermatome; a total score of 112 is possible for each PP and LT.

**Neurologic level of injury:** The most caudal level at which both motor and sensory modalities are intact.

**Complete injury:** The absence of sensory and motor function in the lowest sacral segments.

**Incomplete injury:** Preservation of motor and/or sensory function below the neurologic level that includes the lowest sacral segments.

**Skeletal level:** The level at which, by radiological examination, the greatest vertebral damage is found.

**Zone of partial preservation:** Used only with complete injuries, refers to the dermatomes and myotomes caudal to the neurological level that remain partially innervated. The most caudal segment with some sensory and/or motor function defines the extent of the ZPP.

of pin sensation in the lower sacral segments yields a better prognosis for neurological recovery.

To test for deep anal sensation (DAS), a rectal digital exam is performed. The patient is asked to report any sensory awareness, touch, or pressure, with firm pressure of the examiners' digit on the rectal wall. DAS is recorded as either present (yes) or absent (no).

The maximum sensory score is 112 (calculated by adding the scores from the 28 dermatomes—maximum score of 56 for each side of the body) for LT and pin sensation. The *sensory level* is defined as the most caudal level where sensation for LT and PP are both graded as 2 (normal) for both sides of the body. If the LT level is C6 and PP is C5, the overall sensory level is C5. In a case where sensory loss begins at, or just above the nipple line (T4 dermatome), often a patient is credited with the T3 dermatome being spared. If the sensation is absent in the T1 and T2 dermatomes despite the presence of some sensation at the T3 dermatome it is recommended that the T3 dermatome be scored as absent. It is felt that this sparing above the nipple line is from C4 innervation.

**Motor exam:** The motor exam is conducted using conventional manual muscle testing (MMT) technique (on a scale from 0 to 5) in ten key muscle groups, five in the upper limb (C5-T1 myotomes) and five in the lower limb (L2-S1), on each side of the body (Table 27-2). Key muscles were chosen based upon their myotomal innervations and ability to be tested in the supine position. Most muscles are innervated by two root levels (e.g., the elbow flexors are innervated from C5 to C6). When a key muscle tests initially as a grade 5, it is presumed to be fully innervated by the contributions from the two roots. If a muscle initially grades a three fifth, it is presumed to have full innervation of its more proximal segment (in the case of the elbow flexors, innervation from the C5 myotome). The maximum motor index score is 100 (calculated by adding the scores—maximum of 50 for each side of the body). Voluntary anal contraction is tested by sensing contraction of the external anal sphincter around the examiner's finger and graded as either present or absent.

When examining a patient with an acute injury below T8, the hip should not be flexed passively or actively beyond

90 degrees as this may place too great a kyphotic stress on the lumbar spine. Therefore, it may only be possible to test hip flexor muscle strength isometrically. While asking the patient to lift the leg straight off the bed, the patient's movement is resisted and the examiner's judgment is required to grade the muscle force as 2 through 5.

If a muscle's range is limited by contracture that exceeds 50% of the normal ROM, the muscle is to be listed as NT (not testable); if less than 50% loss of range—the MMT scoring can be applied. NT is also used if the muscle cannot be tested; that is, a cast in place limiting MMT. If spasticity interferes with the exam significantly, then NT should be documented. If pain limits full patient effort and the examiner feels that the initial contraction given represents normal strength, the muscle should be graded as 5\*, while indicating the reason for this scoring (e.g., pain).

The *motor level* is defined as the most caudal motor level with a score of  $\geq 3$ , with the more cephalad key muscles grading a 5. For injuries with no corresponding motor level (i.e., above C4, T2-L1), the last normal sensory level is used. For example, a person with normal strength in all key muscles of the UEs, 0/5 strength in the key muscles of the LEs, with a T4 sensory level, would be assigned a motor level of T4. Similarly, in a case where the elbow flexors (C5 level) grade 3/5 on both sides, with a sensory level on the left at C4 and on the right C3; the motor level on the left would be C5 and on the right C3. This is due to the C4 dermatome on the right being scored as impaired—it is presumed that the C4 myotome is also impaired. Therefore, the motor level is designated as C3, since the patient does not meet the criteria of having a key muscle  $\geq 3/5$ , with the levels above (in this case C4) scoring as normal. On the left side, the C4 dermatome is normal so the C4 myotome is considered normal and as a result, the left motor level is C5.

The NLI is the most caudal level, at which both motor and sensory modalities are intact on both sides of the body. The motor and sensory levels are the same in less than 50% of complete injuries, and the motor level may be multiple levels below the sensory level at 1-year postinjury (51). In cases where there is no key muscle level available (i.e., cervical levels at and above C4; T2-L1; and sacral levels below S2), the NLI is that which corresponds to the sensory level.

If there are non-SCI-related causes of weakness, this should be documented and taken into account when classifying the injury. For example, in a patient with a T8 fracture and complete paraplegia who also has a left brachial plexus injury, notation should be made that the sensory and motor deficits in the left arm are due to brachial plexus injury, not SCI, and the patient may still be classified with a NLI of T8. The motor level and UE motor index score better reflect the degree of function as well as the severity of impairment and disability, relative to the NLI, after motor complete tetraplegia (51).

### AIS Classification

The International Standards have evolved over the past 25 years and have become accepted as the most appropriate method to

describe the neurological impairment of SCI for clinical and research use and have been incorporated into the International Core SCI Data Set. In 1982, the ASIA first published the *Standards for Neurological Classification of SCI*, adopting the Frankel Scale (52). The Standards were replaced in 1992 by the AIS (53) and revised a number of times since (1996 and 2000) with reprinting in 2002 and 2006 (50,53,54).

The patient's injury is classified utilizing the AIS, separating the injury into a neurologically complete versus incomplete injury. A neurologically *complete* injury is defined as an injury with the individual having no "sacral sparing." *Sacral sparing* refers to having one or more of the following residual findings: LT or PP in the S4-5 dermatome (can be on either side, impaired or intact); DAS or voluntary anal contraction preserved. If any of these components are present, the individual has sacral sparing and therefore has a neurologically *incomplete* injury. Patients who have an incomplete injury initially (i.e., sacral sparing) have a significantly better prognosis for motor recovery than those without preservation of the lower sacral segments.

Table 27-3 describes the steps to classify the SCI and Table 27-4 outlines the AIS. A reference manual and training video are available that provide a detailed explanation of the examination elements (ASIA, Atlanta, GA. [www.asia-spinalinjury.org](http://www.asia-spinalinjury.org)). The *zone of partial preservation* (ZPP) refers to the dermatomes and myotomes caudal to the NLI that remain partially innervated in persons with a neurologically complete injury (AIS A). The ZPP should be recorded as the most caudal segment with some sensory and/or motor sparing but only in persons with a neurologically complete injury.

A neurologically complete injury is classified as AIS A. Persons with sensory sacral sparing are classified as an AIS B. To be classified with a motor incomplete injury (AIS C or D), the subject must have either (a) voluntary anal sphincter contraction or (b) sensory sacral sparing with sparing of motor function more than three levels below the *motor level* (50,54). To differentiate an AIS C from D, the individual with a motor incomplete injury AIS D has at least half of key muscles below the *NLI* with a muscle grade of 3 or more (AIS C would be less than half). It is important to recognize the distinction using the motor level to determine if one with sensory sacral sparing has a motor incomplete injury (AIS B vs. C), yet uses the NLI when differentiating an AIS C from D.

### Incomplete SCI Syndromes

Incomplete SCI syndromes include central cord (CCS), Brown-Sequard, anterior cord, conus medullaris, and CE syndromes (CES), and can result from traumatic as well as NT injuries (55). CCS is the most common, accounting for approximately 50% of incomplete injuries and 9% of all traumatic SCI. CCS is characterized by motor weakness in the UE greater than the LE, in association with sacral sparing. CCS most frequently occurs in older persons with cervical spondylosis who suffer a hyperextension injury from a fall, but it may also occur in persons of any age and is associated with other etiologies, predisposing factors, and injury mechanisms (56). The postulated mechanism of the injury involves compression of the

**TABLE 27.3** Summary of the Steps to Determine the Classification of Individual with SCI

1. Determine sensory levels for right and left sides.  
Sensory level = Most caudal segment of the spinal cord where both PP and LT are normal and all rostral segments are normal  
Start from the top of the worksheet, and go down until you see a "1" or "0" for either LT or sharp/dull, and go up one level. That is the sensory level.
  2. Determine motor levels for right and left sides.  
Motor level = The lowest key muscle that has a grade of at least 3, providing that the key muscles ... above that level are normal  
*Note: In regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level.*
  3. Determine the single neurological level.  
*Note: This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the 4 levels (2 sensory, 2 motor) determined in steps 1 and 2.*  
*Single neurological level = The most rostral of sensory and motor levels.*  
*For example, if*  
*Sensory level: Right C4 Left C5*  
*Motor level: Right C5 Left C6*  
*then, single neurological level = C4*
  4. Determine whether the injury is complete or incomplete (sacral sparing).  
*Sacral sparing* = Sensory or motor function in the sacral segments, S4-5.
    - Sensory function = S4-5 dermatome or DAS.
    - Motor function = voluntary anal sphincter.
  5. Determine AIS grade
    - (a) Is injury *incomplete*? No, AIS = A. Record ZPP.  
If the injury is complete, the worksheet will read "N-0-0-0-0-N"
    - (b) If yes, is injury *motor incomplete*? No, AIS = B  
(Yes = voluntary anal sphincter or motor function more than three levels below the motor level on a given side.)
    - (c) If yes, are at least half of the key muscles below the (single) neurological level graded 3 or better? No, AIS = C
    - (d) If yes, AIS = D.
    - (e) If sensation and motor function is normal in all segments, AIS = E.
- Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the AIS does not apply.*

cord both anteriorly and posteriorly by degenerative changes of the bony structures, with inward bulging of the ligamentum flavum during hyperextension in an already narrowed spinal canal (55,56).

**TABLE 27.4** ASIA Impairment Scale

- A = Complete: No motor or sensory function is preserved in the sacral segments S4-5.
- B = Incomplete: Sensory but not motor function preserved below the neurological level and includes the sacral segments S4-5.
- C = Motor function is preserved below the neurological level, and more than half of the key muscles below the neurological level have a muscle grade <3.
- D = Incomplete: Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade of 3 or more.
- E = Normal: Motor and sensory function are normal.

*Note: For an individual to receive a grade of C or D, he/she must be incomplete, that is, have sensory or motor function in the sacral segments S4-5. In addition, the individual must have either (a) voluntary anal sphincter contraction or (b) sparing of motor function more than three levels below the motor level.*

*Source: American Spinal Injury Association. International Standards for Neurological Classification of Spinal Cord Injury. Reprinted 2002. Chicago: ASIA; 2006.*

It has been postulated that the pathophysiology of the upper limbs being more affected than that of the lower limbs is that the motor tracts of the upper limbs are located more centrally, while those of the lower limbs are located more peripherally in the spinal cord (56). MRI evidence has revealed that this clinical pattern may not be based on locations of the arm and leg fibers within the corticospinal tract, but rather that this tract carries fibers that mainly innervate distal limb musculature, and therefore, the functional deficits are more pronounced in the hands when the tract is the primary site of damage (57).

CCS generally has a favorable prognosis for functional recovery. Recovery occurs earliest and to the greatest extent in the LEs, followed by bowel and bladder function, proximal UE, and then distal hand function. Prognosis for functional recovery of ambulation, ADL, and bowel and bladder function is dependent upon the patient's age (< or >50 years of age), with a less optimistic prognosis in older patients (>50 years old) relative to younger patients (55,58–60). Specifically, younger patients are more successful in becoming independent in ambulation (87% to 97% vs. 31% to 41%), bladder function (83% vs. 29%), and dressing (77% vs. 12%) (58) than older patients. Older newly injured individuals, however, with an initial classification of AIS D tetraplegia, have a good prognosis for recovery of independent ambulation (60).

*Brown-Sequard syndrome* (BSS) is defined as a lesion similar to a hemisection of the spinal cord, and accounts for 2% to 4% of all traumatic SCI (55,61–63). In the classic presentation, there is (a) ipsilateral loss of all sensory modalities at the level of the lesion; (b) ipsilateral flaccid paralysis at the level of the lesion; (c) ipsilateral loss of position, sense, and vibration below the lesion; (d) contralateral loss of pain and temperature below the lesion; and (e) ipsilateral motor loss below the level of the lesion. This is due to the crossing of the spinothalamic tracts in the spinal cord, as opposed to the corticospinal and dorsal columns that cross the brain stem. The pure form of BSS is rare and the Brown-Sequard Plus Syndrome is more common (BSPS) (64), which refers to a relative ipsilateral hemiplegia with a relative contralateral hemianalgesia. Although BSS has traditionally been associated with knife injuries, a variety of etiologies, including closed spinal injuries with or without vertebral fractures may be the cause (64,65).

Recovery usually takes place in the ipsilateral proximal extensors and then in the distal flexors (66,67). Motor recovery of any extremity having a pain/temp sensory deficit occurs before the opposite extremity. Overall, patients with BSS have the greatest prognosis for functional outcome of the incomplete syndromes, as 75% to 90% of patients ambulate independently at discharge from rehabilitation and nearly 70% perform functional skills and ADL independently (62,64). In predicting outcome, when the upper limb is the predominant site of weakness, patients are more likely to ambulate at discharge. Recovery of bowel and bladder function is also favorable.

The *anterior cord syndrome* involves a lesion affecting the anterior two thirds of the spinal cord while preserving the posterior columns. This may occur with flexion injuries, from retropulsed disc or bone fragments compressing the cord, direct injury to the anterior spinal cord, or with lesions of the ASA which provides blood supply to the anterior spinal cord (55,62,68). There is a variable loss of motor as well as PP sensation with a relative preservation of LT, proprioception, and deep-pressure sensation. Patients usually have a 10% to 20% chance of muscle recovery (69).

*Posterior cord syndrome* (PCS) has been omitted from recent versions of the International Standards, and is the least common of the SCI clinical syndromes with an incidence of less than 1% (55,62). There is a loss of proprioception and vibration sense, but with preservation of muscle strength, temperature, and pain sensation due to a selective lesion of the posterior columns. PCS has been linked to neck hyperextension injuries, PSA occlusion, tumors, disk compression, and vitamin B<sub>12</sub> deficiency. Prognosis for ambulation is poor, secondary to the proprioceptive deficits.

*Conus medullaris and Cauda Equina (CE) injuries*: The conus medullaris, which is the terminal segment of the adult spinal cord, lies at the inferior aspect of the L1 vertebrae. The segment above the conus medullaris is termed the epiconus, consisting of spinal cord segments L4–S1. Lesions of the epiconus will affect the lower lumbar roots supplying muscles of the lower part of the leg and foot, with sparing of reflex function

of sacral segments. The bulbocavernosus (BC) reflex and micturition reflexes are preserved, representing an UMN or suprasacral lesion. Spasticity will most likely develop in sacral innervated segments (e.g., toe flexors, ankle plantar flexors, and hamstring muscles). Recovery is similar to other UMN spinal cord injuries.

Conus medullaris lesions present with UMN and LMN aspects. Lesions affecting neural segments S2 and below will present with LMN deficits of the anal sphincter and bladder due to damage of the anterior horn cells of S2–4. Bladder and rectal reflexes are diminished or absent, depending on the exact level and extent of the lesion. Motor strength in the legs and feet may remain intact if the nerve roots (L3–S2) are not affected, that is, “root escape.” Trauma and tumors are among the most common etiologies responsible for this condition.

Injuries below the L1 vertebral level usually affect the CE or nerve rootlets supplying the lumbar and sacral segments producing motor weakness and atrophy of the LEs (L2–S2) with bowel and bladder involvement (S2–4), impotence, and areflexia of the ankle and plantar reflexes. CES is a LMN injury. In CES there is a loss of anal and BC reflexes. CE injuries have a better prognosis relative to UMN injuries for neurological recovery, most likely due to the fact that the nerve roots are more resilient to injury as they are histologically peripheral nerves and therefore regeneration can occur. CE injuries may represent a neuropraxia or axonotmesis, and demonstrate progressive recovery over a course of weeks and months. CES can occur as a result of trauma, tumors, spinal stenosis, disc compression, infection, or postsurgical epidural hematoma (55).

Separation of CE and conus lesions in clinical practice is difficult, because some of the clinical features of these lesions overlap. Pain is uncommon in conus lesions but is frequently a complaint in CES. Sensory abnormalities occur in a saddle distribution in conus lesions and, if there is sparing, there is usually dissociated loss with a greater loss of pain and temperature while sparing touch sensation. In CE lesions, sensory loss occurs more in a root distribution and is not dissociated.

## FUNCTIONAL EVALUATION

The International Standards (50) are the most widely accepted instrument of impairment, and interrater reliability is very good overall (70). The Modified Benzel Scale is a 7-grade scale used in the Sygen studies (71) that expands the AIS D category into three separate grades. The International Classification for Surgery of the Hand in Tetraplegia (72) is most commonly used when dealing with upper limb reconstruction procedures. A committee has developed a classification for autonomic functions, including blood pressure (BP), heart rate, and temperature regulation; bladder function; bowel function; and sexual function (70,73).

Functional limitation in SCI can be measured by the Grasp and Release Test that evaluates the impact of implanted upper limb prosthesis (74) or the capabilities of UE instrument

(75,76). To measure walking in a standardized environment as it relates to walking, the Timed Get Up and Go test, 6-minute walk test or 10 m walk have been utilized (70,77). The Walking Scale for SCI (WISCI) is a valid scale that ranks walking based on various combinations of braces, assistive devices, and level of personal assistance (78,79).

Activity performance, what an individual can do in his/her environment, can be measured by the functional independence measure (FIM), the Canadian Occupational Performance Measure, the Quadriplegic Index of Function (QIF), and the spinal cord independence measure (SCIM) (70,80–84). The FIM as a generic instrument has shortcomings when applied to SCI and while the FIM was added to the Standards in 1992 (53), it was removed in the 2000 revisions (54). The QIF and SCIM are more sensitive and a better indicator of motor recovery as compared to the FIM, since it can reflect small gains in function which parallel small strength gains (84,85). The QIF is limited in use to persons with tetraplegia and has been used sparingly. The SCIM addresses indoor and outdoor activities (86) and is gaining in popularity.

Individuals with the same SCI level and severity may have different levels of activity performance due to differences in adaptive equipment, personal assistance, and accessibility of their environment. Impairments are not highly correlated with community integration, that is, the inability to walk does not prevent one from working. The CHART is the most commonly used measure of community functioning (participation) for persons with SCI (87). QOL is not related to impairment, but rather is highly associated with social support, community integration, and resumption of life and family roles (88).

## PROGNOSTICATING NEUROLOGICAL RECOVERY

Prognosticating neurological recovery early after a traumatic SCI is important to provide accurate information to patients and their families and to guide the rehabilitation course. The major factors in predicting recovery early after a traumatic SCI include the initial NLI, the initial motor strength, and most importantly, whether by examination the injury is classified as neurologically complete or incomplete (89). This information is best provided by performing the neurological physical examination using the International Standards (90). The examination at 72 hours postinjury is superior to that at 24 hours postinjury for predicting recovery (91,92).

Between 30% and 80% of patients with initially complete tetraplegia will recover one root level of function. Most UE recovery occurs during the first 6 to 9 months, with the greatest rate of change during the first 3 months. Motor recovery can continue during the second year, especially for patients with initially 0/5 strength. The initial strength of the muscle, immediately below the motor level, is the most significant predictor of achieving antigravity strength by 1-year postinjury (93–95). If the first level below the NLI has 0/5 strength at 72 hours to 1 week, approximately one third of patients will

recover to 3/5 strength in that muscle. If there is some initial strength present, approximately 75% to 95% of patients will regain antigravity strength at 1 year. At 1 month, if there is no motor strength in the first level below the NLI, then only 27% will improve to 3/5 by 1 year (94). Presence of sensation in the dermatome corresponding with that motor level, improves the chances of recovery. The faster an initial 0/5 muscle starts to recover some strength, the better the prognosis for recovery. Only a small percentage of subjects have motor recovery below the first level caudal to the motor level. Recovery at the C4 level to the C5 level, both motor and sensory, may be less and slower than at the lower cervical segments, especially if there is initially no strength at the C5 myotome (96).

Persons with incomplete tetraplegia have a better prognosis for recovery (97,98). UE motor recovery is approximately twice as great in incomplete tetraplegia as in complete tetraplegia, with the potential for varying degrees of LE motor recovery and functional ambulation. For patients who are sensory incomplete initially, the prognosis for motor recovery is more favorable in those with sparing of pin sensation rather than LT sensation alone (92,97–99). The basis of a more favorable outcome for pin sparing may be explained by the close anatomical relationship of the motor tracts (lateral corticospinal tract) to the sensory tracts carrying pain and temperature fibers (lateral spinothalamic tract). Ambulation can be predicted by having PP sensation sparing in 50% or more of the dermatomes in the LE (L2–S1) (99). Up to 40% of patients initially classified as AIS B will improve to AIS C and up to 40% to AIS D (92). Functional and neurological recovery is even more favorable for patients with an initial motor incomplete injury. Approximately 60% to 80% of patients initially classified as AIS C will improve to AIS D. The majority of motor recovery occurs within the first 6 months after injury, and the early return of motor function suggests a better functional outcome. Motor recovery in the UEs and LEs occurs concurrently, rather than sequentially.

In complete paraplegia, the potential for LE motor recovery improves with lower initial NLI; 15% of patients with a NLI between T9 and T11, and 55% of those with an initial NLI below T12, demonstrate recovery of some strength in the lower limbs (100). Most movement gained is in the proximal LE musculature and may represent recovery of partially injured lumbar roots or “root escape.”

Individuals with incomplete paraplegia have the best prognosis for LE motor recovery and ambulation (101). Eighty percent of individuals with incomplete paraplegia regain antigravity hip flexors and knee extensors at 1 year. Individuals with no LE motor control at 1 month may still show significant return by 1 year.

## AIS A Conversion and Late Recovery

The vast majority of patients initially designated as having a complete injury will remain an AIS A. There are older reports of up to 10% of initial AIS A converting to AIS B and 10% regaining some motor function at later follow-up (92,102). Burns et al. reported that at year 1 or later, less than 7% (2/30)

of AIS A subjects initially tested within 2 days without factors affecting exam reliability, converted to AIS B status, and none developed volitional motor function below the zone of injury (103). Aspects of an early examination that may render it unreliable include factors that may affect cognition (i.e., TBI, drugs) and communication barriers (i.e., on ventilator). More recent literature has reported greater amount of conversion from initial to follow up examinations. A comprehensive review of the existing literature by the International Campaign for Cures of Spinal Cord Injury Paralysis (ICCP) reported a conversion rate of ~20% at one year post-injury, with 10% converting to AIS B and an additional 10% regained some motor function (AIS C and D) (104). The conversion rate of AIS A was twice as high for persons with tetraplegia compared to paraplegia. A recent evaluation of the European Multi-center study on human spinal cord injury (EM-SCI) reported that 70% of persons with initial (within 15 days) AIS A remained AIS A at one year, with 17.3% improving to AIS B, 5.8% to AIS C, and 7.2% to AIS D (105). Late conversion (i.e., change in status from a neurologically complete to incomplete injury after 30 days) has been reported to occur in 4% to 10% of cases (92,94,106,107). Late conversion can occur even years after injury, although usually only to AIS B with very few (<2%) to motor incomplete status, or C (108).

### Other Predictors of Neurological Recovery

The presence of spinal shock may play a role in prognosis; for the same degree of SCI, the presence of spinal shock implies a more rapid evolution of injury and a poorer prognosis. The order that reflexes return in the postinjury period may help prognosticate outcome (24,109). Absence of the BC reflex (S3-4 roots) or the anal reflex (S2-4 roots) after the acute period (24 to 72 hours) suggests injury to the conus medullaris or CE (i.e., LMN injury). As such, prognosis regarding recovery and also the potential use of rehabilitation intervention (e.g., electrical stimulation [ES]) can be determined. The delayed plantar response, which may be the first of all reflexes to return, occurs within hours or days following SCI, and its persistence shows a high correlation with complete injuries and a poor prognosis for LE motor recovery and function (ambulation) (109,110). The presence of the crossed adductor response to patellar tendon taps in the acute stage is highly predictive of functional motor recovery (111). Older individuals may have a less favorable outcome in regard to neurological recovery, functional ambulation, and bowel and bladder independence than younger patients with similar severity of the injury, and they have more associated medical complications (112).

Radiological and electrodiagnostic results early after injury assist in confirming the prognosis obtained from the clinical evaluation. The type of fracture often correlates with the severity of the injury. Bilateral cervical facet dislocation, thoracolumbar flexion/rotation injuries, and transcanal bullet locations more commonly occur with neurologically complete injuries. An intramedullary hemorrhage correlates with a more severe initial neurologic deficit, and carries a poorer prognosis. Hemorrhage location corresponds anatomically to the level of the neurologic injury. The greater the extent of cord signal abnormality on MRI,

the greater the chance of having a complete injury (113–116). Lesions in patients with incomplete SCI (AIS B through E) were found to have a mean length of  $\leq 20$  mm, whereas those in patients with neurologically complete injuries had a mean length of 40 mm (116). The presence of cord edema greater than 1 vertebral body segment is also a poor prognostic finding. Smaller degrees of cord edema and especially the absence of abnormal signal intensity on MRI in the spinal cord are considered positive predictors for neurologic recovery. In the chronic stage after SCI, persons with persistent cord signal changes on MRI demonstrate little improvement in AIS grades relative to the improvements of patients with resolution of signal abnormalities.

Electrophysiological techniques include nerve conduction studies, late responses (H-reflex and F-wave), somatosensory-evoked potentials (SSEP), motor-evoked potentials (MEP), and sympathetic skin responses (SSR) that can supplement clinical and neuroradiological findings (89,117–122). These tests, however, are most useful in differentiating lesions between the central and peripheral nervous system. They may also help in diagnosing a neurologically complete versus incomplete injury in uncooperative or unconscious patients, or to rule out a conversion disorder, since they do not require the cooperation of the patient. They are not a routine part of the acute investigation of a newly injured individual to offer prognosis for neurological or functional outcome.

### Nontraumatic Spinal Cord Injury

NT SCI is a growing population for admission to inpatient rehabilitation and includes such etiologies as spinal stenosis with myelopathy, spinal cord compression from a neoplasm, multiple sclerosis (MS), transverse myelitis (TM), infection (viral, bacterial, fungal, parasitic), vascular ischemia, radiation myelopathy, motor neuron diseases, syringomyelia, vitamin B<sub>12</sub> deficiency, and others. Spinal stenosis and spinal cord tumors are the most common causes of NT SCI presenting for inpatient rehabilitation in the United States (123,124).

Details regarding most of these disorders are covered elsewhere in the text. TM is an inflammatory disorder of the spinal cord, with a female to male ratio of 4:1 that peaks in the second and fourth decades. TM most commonly affects the thoracic spine (50%) and diagnosis is best established by MRI. The time course of progression of symptoms that include back pain, motor weakness (the UEs are less often involved), abnormal sensations, and neurogenic bowel and bladder, is from hours to weeks. Although some patients recover with minor or no residual problems, most remain with residual permanent impairments. Poor recovery is predicted by rapid progression, back pain, and spinal shock (125). Most patients will have only one episode of TM, but a small percentage may have a recurrence.

SCI from epidural abscess is most commonly seen in immunocompromised and diabetic patients. *Staphylococcus aureus* is the most common pathogen. Epidural hematoma can be associated with anticoagulation, vascular malformations, or myelodysplastic diseases. Arterial disease from a thrombus or embolism to the spinal arteries or from other vascular diseases, including vasculitis and diabetes, or from thoracoabdominal aneurysm repair (reported in 9% to 18% of cases), may cause spinal cord ischemia/infarction.

Late radiation myelopathy is a delayed complication of radiation to lesions of the spine or adjacent tissues that develops months or years after treatment. The incidence of this complication is correlated with the total radiation dose, the dose fraction, and the length of the spinal cord irradiated. Clinically, there is weakness, loss of sensation, and sometimes a Brown-Séquard like syndrome develops. The injury predominantly affects the white matter in the lateral spinal cord. The diagnosis of late radiation myelopathy remains one of exclusion and prognosis for significant recovery is poor.

Spinal cord tumors can be primary or metastatic, intradural, or extradural (see Chapter 43 for details). The majority of spine and spinal cord tumors are metastatic in origin and 95% are extradural. Approximately 70% of spinal metastasis occurs in the thoracic spine, with clinical presentation of pain, which is typically worse at night and in the supine position. Neurological changes including weakness, sensory loss, and bowel/bladder involvement indicates cord involvement. The most common sources of secondary tumors are metastatic lung, breast, and prostate. The strongest predictors of functional outcome are the tumor type and the preoperative neurological status (126).

As compared to persons with traumatic-related SCI, individuals with NT SCI are more likely to be older, female, married, and retired. NT SCI is more common than trauma in persons over 40. Persons with NT SCI usually have a less severe neurological impairment as compared with traumatic SCI, as they more often present with motor incomplete (90%) lesions (127). There is a lower incidence of secondary medical complications including spasticity, orthostasis, deep vein thrombosis (DVT), PUs, autonomic dysreflexia (AD), and wound infections during rehabilitation in patients with NT SCI (128–130). However, because cervical stenosis and neoplastic SCC has a peak incidence between the ages of 50 and 70 years, these individuals may have other premorbid medical issues that may impact their rehabilitation. No difference is noted for depression, urinary tract infections (UTIs), heterotopic ossification (HO), pain, or gastrointestinal (GI) bleeds.

No statistical differences were found in acute care LOS and admission to rehabilitation FIM scores (123,127,131) in patients with NT SCI relative to traumatic SCI. Inpatient rehabilitation LOS are shorter for persons with NT injury secondary to tumors, but FIM efficiency and home discharge rates are overall comparable to traumatic SCI. There is a favorable discharge to home for patients who have an incomplete injury, are married, have an established bowel and bladder management program, intact skin, male gender, and who are cognitively intact.

## Rehabilitation of SCI

Rehabilitation begins in the intensive care setting and includes addressing the SCI-specific needs to help the individual meet their potential in terms of medical, physical, social, emotional, recreational, vocational, and functional recovery (132). If early medical complications can be prevented, the inpatient rehabilitation course is facilitated, and the total cost of care is lessened.

The medical aspects of the SCI specialist's acute recommendations can be formulated into a problem list (Table 27-5). The most important aspects include bowel, bladder and pulmonary

**TABLE 27.5** Sample Problem List for Acute Care SCI Rehabilitation Consultation

Medical Problem List	Interventions
Respiratory	Monitor VC, if tetraplegia Perform incentive spirometry, assisted cough techniques, deep breathing techniques, chest PT, and respiratory treatments
Gastrointestinal Nutrition	Stress ulcer prophylaxis Perform calorie count Monitor weekly weights
Neurogenic bowel	Initiate bowel program and adjust as needed
Neurogenic bladder	Patient and family training Proper intake and output Discuss bladder options Family training
DVT prophylaxis	Pharmacological prophylaxis Monitor LE circumference Check duplex study upon admission to rehabilitation
Skin	Proper mattress Turn Q 2 degrees initially Heel protectors Frequent weight shifts. in w/c Proper cushion Teach patient to use mirror to check skin
Orthostasis	Change positions slowly Ace wrap or LE stockings and abdominal binder Use tilt table and pharmacological intervention, if needed
HO	Monitor hip and knee ROM X-rays and bone scan, if suspected
Spasticity	Stretching/ROM Modalities Medications Injections
Autonomic dysreflexia	Monitor closely
Hypercalcemia	Monitor for symptoms Fluids, medications
<b>Rehabilitation issues</b>	
Mobility	ADL
Adjustment to disability	Cognitive
Communication	Swallowing
SCI education	Vocational
Sexuality	Driving
Recreation	Family training
Discharge planning	Equipment evaluation

management, deep venous thrombosis, GI prophylaxis, and proper positioning in bed to prevent contractures and skin breakdown, with the proper turning frequency (at least every 2 hours). Once the spine is stabilized by surgery or orthoses, therapy and nursing will incorporate ROM that will help prevent contractures. The shoulder, elbow, hip flexors, and heel cords are most important to range because they are the most

frequently observed contractures on presentation to the acute rehabilitation unit and can potentially serve as a source of pain and functional limitation. Resting splints for paralyzed UEs help prevent contractures and increase comfort. Functional splints may also be useful for feeding and other self-care skills in the early period. For persons with high level tetraplegia who have undergone tracheostomy, early introduction of communication aids is important. Once medically stable, the patient should be transferred to a specialized spinal cord rehabilitation unit.

A specialized SCI center is most beneficial to provide for comprehensive management as it offers access to experienced SCI physicians and therapists, including psychology, vocational and SCI educational services, an active peer support program, and an opportunity to undergo rehabilitation with other patients who have similar impairments (133). A comprehensive SCI education program is essential for educating the patients and their families about SCI-related issues. Additional opportunities available at larger SCI centers include availability of trial equipment for mobility and accessibility to high level assistive technology. The interdisciplinary approach of the rehabilitation team, including the patient and family, is important for the optimal care of the individual with SCI. A sample rehabilitation prescription is listed in Table 27-6. As the LOS shortens in acute rehabilitation, coordination and communication with the entire team is needed to allow for a timely and safe discharge. Frequent team conferences with an early home evaluation are recommended.

### Functional Goals

Once the patient's motor level of injury, AIS, and prognosis for neurological recovery are determined at the onset of rehabilitation, short- and long-term functional goals are formulated and a therapy prescription established. The CPG on outcomes following traumatic SCI delineates expected (at 1 year postinjury) functional outcomes, and equipment needs based on the level of injury for persons with SCI with a motor complete injury (134). Table 27-7 lists the expected functional outcome at 1 year postinjury and Table 27-8 lists equipment usually prescribed for persons for each level of injury.

The projected long-term goals are a starting point for the rehabilitation prescription. The rehabilitation program should be individualized to meet each person's strengths, weaknesses, and individual circumstances. Monitoring progress at the team conference, with the patient as an active participant, helps to identify limiting factors along with the patients' additional needs. Discharge planning should be discussed as early as the first team conference, assuring a timely, but most importantly, a safe discharge. The ideal outcome may not always be achieved for each patient, as there is a significant amount of variability in individual outcomes despite similar levels of injury based upon the age, gender, and medical comorbidities.

### C1-4 Level

Persons with motor levels above C3 will usually require long-term ventilator assistance, whereas most individuals with

**TABLE 27.6 Sample Physical and Occupational Therapy Prescription**

#### Diagnosis: C7 ASIA A Tetraplegia

#### Goals: (see outlined goals)

**Precautions:** Skin, respiratory, sensory, orthostasis, safety, risk for AD, and others as needed for the specific patient (i.e., bleeding if on Coumadin).

#### Physical therapy

PROM to bilateral LE, with stretching of hamstrings and hip extensors.

Mat activities.

Tilt table as tolerated. Start at 15 degrees, progress 10 degrees every 15 min within precautions, up to 80 degrees.

Sitting balancing (static and dynamic).

Transfer training from all surfaces including mat, bed, wheelchair, and floor.

Wheelchair propulsion training and management.

Teach and encourage weight shifting.

Standing table as tolerated.

Deep breathing exercises.

FES for appropriate candidates.

Family training.

Community skills.

Teach home exercise program.

#### Occupational therapy

Passive, active assisted, active ROM/exercises to bilateral UEs.

Allow for some finger tightness to enhance grasp.

Bilateral UE strengthening.

Motor coordination skills.

ADL program with adaptive equipment as needed (dressing, grooming, feeding).

Functional transfer training (bathroom, tub, car, etc.).

Splinting and adaptive equipment evaluation.

Desktop skills.

Shower program.

Kitchen and homemaking skills.

Assistive technology devices, as needed.

Wheelchair training (parts and management).

Home evaluation.

Family training.

Teach home exercise program.

lesions at C4 will be able to wean off the ventilator. Respiratory equipment including a ventilator, a method for secretion management (i.e., suction machine or mechanical insufflator/exsufflator), back-up ventilator batteries, and a generator in case of power failure, should be obtained. Contact should be made with the local power company and emergency services to alert them of the patient's needs prior to discharge.

Rehabilitation goals for persons with high cervical SCI primarily include prevention of secondary medical complications, education and training of the patient and family members, prescription of appropriate durable medical equipment (DME), and environmental modification. The patient should be independent in instructing others in providing care including weight

**TABLE 27.7** Projected Functional Outcomes at 1 Year Post-Injury by Level

	C1-4	C5	C6	C7	C8-T1
Feeding	Dependent	Independent with adaptive equipment after set up	Independent with or w/o adaptive equipment	Independent	Independent

ADL (grooming, feeding, dressing, bathing)	Independent		Independent		Independent
B/B	Independent		Independent		Independent
Transfers	Independent		Independent		Independent
Ambulation	Standing in frame, tilt table or standing wheelchair.		Household ambulation with orthoses.		Community ambulation is possible
Braces	Exercise only Bilateral KAFO forearm crutches or walker		Can trial ambulation outdoors KAFOs, with forearm crutches		Possibly KAFO or AFOs, with canes/crutches

shifts, ROM, positioning, donning orthoses, transfers, and in setting up their environmental control unit (ECU). Additional goals include independence in power wheelchair mobility, using breath control, mouth stick, head array, tongue, or chin control mechanisms. The wheelchair should be equipped with a pressure relief cushion and recline and/or tilt features for independent pressure relief. If the patient can control a power chair, then both a power chair and a manual positional wheelchair with a high back and tilt or recline should be prescribed for use as a back-up wheelchair for assisted mobility in the home and in the community as needed (136). Once properly set

up, persons at these levels of injury should be independent in using assistive technology. This includes lower level technology devices (i.e., adapted phones and page turners) and higher level devices (known as electronic aides of daily living [e-ADL]) that control one or more electronic appliances (i.e., television, radio, lights) via voice activation or switch access. These will allow for independence in communication and controlling their local environment. A type of lift to assist in transfers and a padded commode/shower chair should be prescribed. An attendant-operated van with a lift and tie-down, or accessible public transportation is necessary for community mobility.

The patient's family and social support, financial resources, personal preferences, educational, vocational and avocational goals, and living arrangements after discharge must be fully considered during rehabilitation. Post-acute medical, psychosocial, and rehabilitation care should be prescribed in the home or outpatient setting. Although the evaluation process requires input from many specialist team members, the physiatrist is ultimately responsible for medical justification of all equipment decisions and should be directly involved in the DME evaluation and prescription process.

Restoring respiratory function for persons with high level of injuries (C2 and above) have been achieved by the use of various ES (see later under pulmonary section). These procedures may assist in weaning off of the ventilator, and enhance speech production and improve QOL (135,136).

Persons with a NLI at C4 who have some elbow flexion and deltoid strength may be able to use a mobile arm support (MAS) or balanced forearm orthosis (BFO) to assist with feeding, grooming, and hygiene. Once the elbow flexors have antigravity strength with adequate endurance, these devices are

no longer needed. A long straw or a bottle that the person can easily access to drink fluids should be obtained as early as possible.

The benefit of specialized acute inpatient rehabilitation for persons with such high levels of injury is justifiable despite their inability to initially tolerate 3 hours a day of therapy and having what may seem as limited goals. The SCI medical and nursing care during the first few months after injury are crucial for monitoring, treating, and preventing medical complications that can lead to future morbidity and mortality. Patient and family education, emotional and social support, and exposure to advanced technology that may allow independence in the proper environment (i.e., power mobility, assistive technology) may be the difference between returning to their family/community and living in a long-term facility.

### C5 Level

The C5 motor level adds the key muscle group of the elbow flexors (biceps), as well as the deltoids, rhomboids, and partial innervation of the brachialis, brachioradialis (BR), supraspinatus, infraspinatus, and serratus anterior. It is important during the acute period after SCI to prevent elbow flexion and forearm supination contractures caused by unopposed flexion activity by stretching, splinting, and if needed antispasticity injections. A long opponens splint, with a pocket for inserting different utensils (i.e., Universal cuff), is important to assist with many tasks including feeding, hygiene, grooming, and writing. Most functional activities will require the use of assistive devices; however, tendon transfers may be considered after neurological recovery is complete.

The addition of the elbow flexors should allow for use of a joystick for a power wheelchair and can allow manual wheelchair propulsion on level surfaces with either rim projections (lugs) or plastic-coated handrims with a protective glove. A power wheelchair, with a power recline and/or tilt mechanism, is usually still required in addition to the manual wheelchair. Push rim-activated power-assist wheelchairs may also be advantageous. These are manual wheelchairs that have a motor linked to each rear hub. With each manual propulsion by the user, there is supplementary power provided by the motor. Therefore, the force required by the user for propulsion over the same distance is decreased when compared to a regular manual wheelchair. This feature is particularly useful for those with tetraplegia or those with paraplegia, and overuse injury causing shoulder pain. The use of power-assist wheelchairs can improve the ADL in persons with tetraplegia, when compared to the use of regular manual wheelchairs (137).

Another recent significant wheelchair development is the Independence iBOT 4000 Mobility System. One of its unique functions is the ability to negotiate curbs and stairs. The iBOT is not necessarily appropriate for all power wheelchair users, as there are certain prerequisites that the user must meet. In order to climb the stairs, adequate UE function to grab the handrail and to stabilize the iBOT while initiating the climbing movement is necessary or this can be performed with the assistance of a caregiver.

Persons with this level of injury will require almost total assistance for their bowel program. A padded commode/shower chair is recommended as the gravity from the upright position assists with the program and the padding helps to prevent skin breakdown. Bladder management is a decision based upon discussion with the SCI specialist and urologist, urodynamic results, amount of assistance available, and lifestyle circumstances. Intermittent catheterization (IC) usually cannot be performed independently, and will need to be performed by another person. If using a leg drainage bag, electronic devices to help empty the bag are available. Driving a specially modified van is possible at this level, with a lift for access allowing the patient to be fully independent in this activity.

### C6 Level

The C6 level adds the key muscle group that performs wrist extension (extensor carpi radialis), as well as partially innervating the supinator, pronator teres, and latissimus dorsi. Active wrist extension can allow for tenodesis, the opposition of the thumb and index finger with flexion as the tendons are stretched with wrist extension. One should avoid overly stretching the finger flexors initially after injury (“selective tightening”) in C5 and C6 motor level patients to avoid potentially losing the tenodesis action. Tenodesis may allow some individuals with this level of injury to perform activities without splints, that is, feeding. Tenodesis splints can be fabricated but are frequently discarded by patients.

Feeding, grooming, and UE hygiene are usually independent after assistance with setting up the utensils; however, clothing modifications such as Velcro closures on shoes, loops on zippers, and pullover garments are recommended. Assistance for meal preparation and for other homemaking tasks is still required. Transfers may be possible using a transfer board and with loops for LE management, but most often requires assistance. Although persons with a C6 motor level can propel a manual wheelchair with plastic-coated rims, a power wheelchair is often required for long distances, especially if the individual will be returning to the workplace. Power-assist wheels may be of benefit as well. IC may be possible for males after assistance for set-up with assistive devices (138) but this technique is more difficult for females.

### C7, C8 Levels

The C7 motor level adds the elbow extensors (triceps) as the key muscle group; C8 the long finger flexors. The C7 level is considered the key level for becoming independent in most activities at the wheelchair level, including weight shifts, transfers between level surfaces, feeding, grooming, upper body dressing, and light meal preparation (139). Uneven surface transfers, lower body dressing, and house cleaning may require some assistance. The independent use of a car is possible if the individual can transfer and load/unload their wheelchair.

IC in males can be performed although it is more difficult for females, especially if LE spasticity is present. Surgical options for females including a continent urinary diversion with an umbilical stoma can allow for a cosmetic means to

catheterize easily (140). Bowel care on a padded commode seat, especially suppository insertion, may still require assistance or the use of adaptive devices (i.e., suppository inserter).

### T1-12 Thoracic Levels

Individuals with all levels of paraplegia should be independent with basic ADL including LE dressing, and mobility skills at the wheelchair level on even and uneven surfaces. This includes advanced wheelchair techniques such as curbs, ramps, wheelies (balancing the wheelchair on the two rear wheels), and floor to wheelchair transfers. Bowel and bladder management should be independent.

For most individuals with higher levels of complete thoracic injury, community ambulation is not a functional long-term goal. The lower the level of injury, the greater the trunk control due to abdominal and paraspinal muscle innervation. For lower levels of thoracic injuries, there is improved trunk control to allow for ambulation training with bilateral LE orthoses, as an exercise and for short distance household ambulation, once they have mastered basic wheelchair mobility skills.

### L1-2 Levels

Muscles gained at these levels include the hip flexors and part of the quadriceps. While the person may be able to ambulate for short distances, a wheelchair will still be required for functional mobility needs. Bladder care is usually by IC. Individuals with these levels of injury can drive a car with hand controls.

### L3-4 Levels

The knee extensors are fully innervated with some strength of ankle dorsiflexion (L4 myotome). Ambulation usually requires ankle foot orthoses (AFOs) with canes and crutches. Bowel and bladder management should be independent. These injuries are, typically, LMN in nature, and bowel management is usually by contraction of abdominal muscles and manual disimpaction. Suppositories will not be effective because of the loss of sacral reflexes. Bladder management is usually performed via IC or valsalva maneuver if postvoid residuals are within normal limits and urological work-up reveals no contraindication to this method. Absorbent pads can be used.

### L5 and Below

These individuals should be independent in all activities unless there are associated problems, that is, severe pain, cardiac conditions, etc.

## Specific Activities in Therapy

### Range of Motion

Shoulder ROM is important to prevent pain in persons with all levels of injury. In persons with C5 and C6 motor levels, ROM should be especially addressed to diminish the development of elbow flexion and supination contractures. As previously mentioned, for those individuals with active wrist extension and weak or no finger function, the finger flexors should not be fully stretched, but instead, allowed to tighten somewhat and naturally curl to improve grip strength and function utilizing a

“tenodesis” action. Lying prone when medically able is helpful in preventing and stretching the hip flexors. Prevention of heel cord tightness and contracture is important for proper positioning of the feet on the wheelchair footplate. Stretching of the lumbar spine is initiated when tightness or spasticity interferes with function, but is often avoided to provide the patient with increased postural stability and balance in the short and long sitting positions.

### Modalities

Modalities such as heat, cold, and ultrasound can be used above the level of the sensory loss, but in areas with diminished or no sensation, one must be cautious as the risk of causing a burn is high.

### Pressure Reliefs

Pressure reliefs are essential to prevent the occurrence of PUs. When supine, turning is initially performed every 2 hours and is progressively extended with close monitoring for signs of erythema that does not quickly dissipate (i.e., early stage one pressure sore). The use of a mirror will greatly enhance the ability to monitor the sacral area and ischial tuberosities (ITs). Persons with high level injuries (at C5 and above) will usually require a wheelchair with a tilt and/or recline mechanism. Some individuals with a C5 motor level can perform an anterior weight shift (with loops attached to the back of the wheelchair to assist in returning to the upright position), or a lateral weight shift. These weight shifts are more effective in pressure relief than having someone tip the wheelchair backward to 35 or 65 degrees (141). Individuals with an injury at C7 and below are usually able to perform independent push-up pressure relief, although other types of weight shifts are still recommended. A pressure relief should be performed for up to 2 minutes every 20 to 30 minutes while in the wheelchair (142). Computerized pressure mapping can be used to locate areas of high pressure in the patient's wheelchair cushion and serve as a teaching tool to demonstrate the pressure relief technique that provides the best results (143).

### Transfers

Initially, transfer training can be started on the mat, with subsequent progression to functional surfaces. Transfer training involves both the patient and the care providers. A lift transfer (one or two persons) is for individuals who are dependent for transfers. These can be performed with a lift that may be manual or electric; free standing, rolling, or attached to a structure (i.e., ceiling). Stand-pivot transfers are for patients who can weight-bear through the LEs with sufficient extension ROM in the hips and knees. Transfer (often referred to as “sliding”) board transfers allow transfer between seated surfaces, with the use of a board that bridges the gap between them. One should, however, be careful not to slide across the board, preventing shearing forces leading to skin breakdown. The board is a sturdy, smooth, flat surface that is made of wood or plastic and comes in different sizes, styles, and handgrips for different transfer situations. The use of the board may decrease

the pressure on the shoulders relative to a sit-pivot transfer. Sit-pivot transfers are performed by patients with a strong upper body, good short sitting balance, and good control of the head and shoulder movements. An overhead swivel trapeze bar can be attached to the bed, with the person lifting their body up swinging across to another surface. This can be a source of shoulder pain and is not recommended to be used on a consistent basis. Floor to chair/chair to floor transfers are particularly useful in accidental situations such as a fall, when the individual can then return to the wheelchair independently. This is a physically demanding technique, requiring strong upper body strength in both the arms and the shoulders.

When transferring into the wheelchair, positioning is critical. The wheelchair should be positioned next to the surface being transferred to, at about a 30 to 45 degrees angle to it. The brakes should be locked and the footrest and armrests should be out of the way. The transfer technique and method used should take into account the presence of PUs at surfaces such as the sacrum and the IT.

Generally speaking, individuals with paraplegia should be independent of transfers, whereas those with tetraplegia may have varying levels of transfer independence. In most instances, those with a NLI at or below C7 can perform independent transfers, with or without the use of a transfer board, though some individuals with a C6 injury may be independent with the board. Individuals with a C5 injury are expected to seek the assistance of one person with or without a transfer board, whereas individuals with an injury at or above C4 will be dependent. The exact transfer technique used by individuals with SCI varies tremendously. Devices such as cushions to raise the seat height, frames, and mechanical devices that can also assist individuals with SCI to stand up may be very helpful in transfers.

### Standing

Standing with the use of a tilt-table or standing-frame, after an acute SCI, decreases hypercalciuria and may retard or lessen bone loss (144); however, it has not been shown to reverse osteoporosis in chronic SCI. Standing should proceed with caution in patients with chronic SCI since bone mineral density is often at or below fracture threshold (145). Additional physiologic benefits of standing include a decrease in spasticity, enhancing bowel and bladder programs secondary to the effect of gravity, and preventing PUs by facilitating pressure relief on normally weight-bearing areas (146,147). Tilt tables can be used early in the rehabilitation process in the treatment of orthostatic hypotension (OH).

### Ambulation

There are four general levels of ambulation; community, household, ambulation for exercise, and nonambulatory (148). Community ambulation requires independence in performing transfers, capable of going from the sit to stand position, and ambulating unassisted in and outside the home for reasonable distances (>150 ft) with or without braces and assistive devices. Household ambulation is the ability to ambulate only within the home with relative independence, but may require

assistance for transfers. Ambulation for exercise is for a person who requires significant assistance for ambulation.

Physiological benefits of walking includes potentially decreasing the progression of osteoporosis, reducing urinary calculosis and spasticity, aiding in digestion and improving the bowel program because of the effect of gravity, and preventing PUs as with standing (149,150). In addition, standing and walking enables reaching objects not obtainable from the wheelchair level and affords access to areas that are not wheelchair-accessible, such as through narrow doorways or into a bathroom that is not appropriately modified. While ambulation following SCI has physiological and psychological benefits, it also has significant drawbacks including increased energy consumption, with decreased speed of ambulation when compared to the relatively normal energy expenditure and velocity of wheelchair use; weight-bearing through the UEs that may predispose an individual to shoulder, elbow, and wrist problems; and poor long-term follow through (151–153).

Community ambulation requires bilateral hip flexor strength >3/5, and one knee extensor to be at least 3/5, with a maximum amount of bracing of one long leg and one short leg brace (148). Prognosis for ambulation can be done early after injury and is determined by the initial level of the injury and the AIS classification (94,98,101). Forty-six per cent of persons with incomplete tetraplegia advance to community ambulation at 1 year, with an additional 14% performing household ambulation. Patients with initially motor complete injuries have a greater chance of ambulation than those with initial sensory incomplete injuries. For those with AIS B, PP sparing offers a better prognosis for regaining the ability to ambulate. Approximately 5% of complete paraplegics (the lower the level of injury, the greater the chance of ambulating) and 76% of incomplete paraplegics regain community ambulation. The percentage of persons with incomplete tetraplegia able to achieve community ambulation is lower than for incomplete paraplegia with equivalent lower extremity motor strength (LEMS), because the UE strength may be compromised and insufficient to enable assistive device ambulation if required. AIS grades at inpatient rehabilitation admission are helpful in predicting walking at discharge. Approximately 28% of persons with AIS C and 67% with AIS D at rehabilitation admission will regain the ability to ambulate by discharge. While level of injury does not significantly affect walking, age more than 50 does have a negative affect on walking in subjects with AIS D (154).

A number of orthotic options exist to assist in ambulation, including mechanical orthoses, functional ES (FES), and hybrid orthoses (a combination of a mechanical orthosis and FES) (155). The knee-ankle-foot orthoses (KAFOs) are most frequently prescribed for ambulation. Other devices used occasionally include the Parawalker, the reciprocal gait orthosis (RGOs), advanced RGO (ARGO), hip-knee-ankle-foot orthoses (HKAFOs), and the hip guidance orthosis (HGO), that may enable persons with thoracic level paraplegia to ambulate. The Parastep system is the simplest example of a FES system for walking (156,157). Newer FES systems are being developed for both standing and walking (158) (see Chapter 48).

The use of partial body weight-supported treadmill training (PBWSTT) for ambulation as a rehabilitation intervention has gained a lot of recent attention. PBWSTT is based on the principle of generating normative, locomotor-like sensory input to promote the recovery of the spinal cord neural circuitry (159,160). With PBWSTT, the weight of the individual is partially supported by an overhead harness, while the therapists assist the hips and the legs of the individuals to walk on the treadmill. Studies in animal models and persons with incomplete SCI have shown improvement in acute and chronically injured individuals, in their ability to learn to walk (161,162). A multi-center trial of 146 subjects with acute neurologically incomplete injuries undergoing conventional training versus PBWSTT, did not find a significant difference in subjects regaining the ability to ambulate (163,164) although there are some significant limitations of this study. There is optimism that this form of therapy is beneficial and additional studies are underway to determine the effectiveness of this modality in the rehabilitation of the patient with acute and chronic SCI. PBWSTT with automated robotic systems are also available (e.g., Lokomat, Hocoma AG), although there is no evidence that robotic PBWSTT will produce superior outcomes to conventional PBWSTT (165).

### Assisted Technology Devices (ATDs)

ATDs serve as the control center to allow for control of electrical appliances in the patient's environment, including the radio, television, bed, computer, lights, etc. The correct ATD can enhance a person's life by giving them a sense of control, security, and independence. One can use any body part to activate a switch as long as they can perform the activity consistently. Reliable activating sites include the head, chin, mouth, shoulder, arm, or hand. Voice activation is also an option. Prior to prescription, it is important to identify the patient's capabilities (i.e., cognitive status and functional movements) and needed tasks, the patient's goals, as well as any environmental barriers that may be present (166).

The use of brain-based command signals for controlling assistive technology, robotics, or neuroprostheses is a newer area of rehabilitation research that may prove to be useful for persons with high level tetraplegia. Brain signals are collected and processed through electrodes that may be placed or implanted at different levels. Once a signal is processed, it can potentially be used to control a number of devices, including computers linked to neuroprosthetic or robotic devices for assistance with ADL (167). There is no clinical product available for brain-based command signals at present and more research is necessary for its application.

### Home Modifications for People with SCI

A number of general guidelines and recommendations for making the home accessible are listed in Table 27-9. A home evaluation or a floor plan of the residence should be completed early as an important aspect of the rehabilitation process to allow the injured individual to return home. The key pieces of information to know when performing the home evaluation

**TABLE 27.9** General Recommendations for Accessibility in the Home

- Outdoor walkways must accommodate a slope of 20" length to every 1" height as the maximum grade.
- Ramps must recognize a 12" length for every 1" rise.
- The minimum space for turning around is 5' × 5' for a manual wheelchair, and 6' × 6' for a power wheelchair.
- Doorway widths that require a "straight shot" (no turning involved) is 32" for a manual chair and 34" for a power wheelchair. This space increases to 36" if there is a turn involved.
- All thresholds should be no greater than 1" to allow the person in the wheelchair to maneuver.
- Install carbon monoxide detectors and smoke alarms throughout the home.
- Low-pile carpeting or hard surface flooring is recommended for wheelchair maneuvering.
- There should be two means of exit from the residence if possible in case of emergency.
- Eliminate throw rugs as they pose a hazard for people who are walking and are difficult for people in wheelchairs to roll over.
- Remove or rearrange furniture that will impede wheelchair access.
- Notify police/fire departments that an individual with a disability resides in the home and provide the bedroom location.
- An intercom system can be useful to allow for communication.
- Backup power should be provided if the person with a SCI is dependent on equipment for life support, such as a ventilator.
- Light switches should be at a height of no more than 36".
- Fireplace/heater cautions: Wheelchairs are generally constructed of some type of metal which may or may not conduct heat, therefore, when a person in a wheelchair is seated near a fireplace or heater, care should be taken to cover the metal parts of the wheelchair that may contact the person's skin, to ensure that the person in the wheelchair does not get burned.
- Power door openers can be installed for people in wheelchairs, where a remote can be used, or install a push plate on the wall.

are the patient's level of injury and mobility status, their prognosis for functional recovery, social situation for return to home, and financial considerations. The main areas to be evaluated include the entrances, bedroom, bathroom, and kitchen, and general safety issues ensuring that there is safe wheelchair access and egress and space to maneuver a wheelchair in the home. The home should be free from fire, health and safety hazards, and an adequate heating, cooling, and electrical supply to meet the needs of additional medical equipment that must be present.

### Driving after SCI

Most individuals with a motor level at or below C5 have the potential to return to independent driving with the appropriate adaptive equipment. The driver rehabilitation specialist evaluates the patient, assists in choosing the proper vehicle, and recommends modifications required including proper controls, lifts, lockdown, and tie-down devices.

A person with complete paraplegia and no additional complications will probably require mechanical hand controls and a few additional minor pieces of equipment to operate a car with an automatic transmission. The evaluation and training for such individuals can usually occur within 3 months of injury. Individuals with tetraplegia are usually evaluated at a later time postinjury (up to 1 year) to allow for neurologic recovery to plateau, since any gain in motor function can mean a difference in equipment required. Higher level injuries (C5 and some C6) require more extensive adaptations allowing for acceleration, breaking, and steering. For lower level tetraplegia, steering may be facilitated by a spinner knob or other devices. In all cases, the person should be medically stable and be psychologically ready to return to the road.

A predriver assessment should be performed and includes a current and past driving history, current medications, a vision screen, physical skills testing (i.e., ROM, strength, sensory and proprioception testing, balance, spasticity, transfer, and wheelchair loading skills), wheelchair or mobility equipment required and reaction time (168,169). If the individual has a history of brain trauma, cognitive and perceptual screens should also be included. The behind the wheel assessment involves vehicle entry and exit, and operation of primary and secondary controls. Training time can range from a few hours for mechanical hand controls and standard steering, to over 40 hours for joystick drivers.

For most persons with paraplegia an automatic transmission car is an option if there are no problems with transfers. Transfer aides are available that can raise the person up to the level of a full size truck seat, but these are costly. If transfers or chair loading are more difficult, then vans should be considered. Loading devices can assist the client in loading the wheelchair. Options include car top devices that fold the manual wheelchair and stow it in a rooftop carrier, or a lift that can stow the folding chair behind the driver's seat. Most persons with tetraplegia choose a modified van with power door openers and a ramp or lift. Persons with a NLI above C5, will require a van to accommodate their transportation needs, but will not be able to drive independently. It is usually easier to transport the person seated in their wheelchair that is already set up to provide the proper support. A structurally modified full-size van or lowered-floor minivan will usually be required. For the dependent passenger, the lowered floor drops their eye height to a point where they may be able to see out the side windows.

## MEDICAL ISSUES AFTER SCI

### Thromboembolic Disorders

Thromboembolic disorders, including DVT and pulmonary embolism (PE), are common medical complications after SCI. The incidence of DVT during the acute postinjury period in older studies varied depending on the method of detection used for screening, and has been reported in approximately 64% of patients (range of 47% to 100%) (170,171). Model system data reported an incidence of 9.8% for DVT and

2.6% for PE during acute rehabilitation (172). The development of DVT occurs most frequently during the first 2 weeks (approximately 80% of cases) following injury. PE occurs in approximately 5% to 8% of patients in the first year and is the third leading cause of death in all SCI patients in the first year postinjury (21,173).

The high incidence of DVT/PE in persons with SCI is related to Virchow's triad that includes stasis, intimal injury, and hypercoagulability; which are all sequelae of acute neurologic injury. Suspicion should be high, and diagnostic testing ordered to make the proper diagnosis if suspected. Clinical signs of a DVT may include unilateral edema, low-grade fever, and pain/tenderness in a patient with an incomplete injury. However, the physical exam is limited in SCI because edema may be present secondary to immobilization and the patient may have loss of sensation. For this reason, screening for DVT is recommended at rehabilitation admission (by duplex ultrasound) and perhaps even during the rehabilitation course (174–176). Clinical signs of a PE may include fever, tachypnea, dyspnea, tachycardia, chest pain, or hypotension.

The consortium guideline on thromboembolism in SCI recommends that patients receive both a method of mechanical prophylaxis of DVT and anticoagulant prophylaxis (177). Pneumatic compressive devices are recommended during the first 2 weeks following injury. If this measure is delayed for more than 72 hours after injury, a duplex scan to exclude the presence of lower limb clots should be performed. It is not clear if patients who are participating in therapy and not utilizing these devices full time should use them on a limited basis. While ES has been shown to be effective, this is rarely used. Anticoagulant prophylaxis should be initiated within 72 hours following SCI provided there is no active bleeding or contraindications such as evidence of head injury or a coagulopathy. Most often low molecular weight heparins (LMWH) are used, with varying opinions as to specific medications and dosages, although dose adjusted or scheduled (two to three times per day) unfractionated heparin has also been utilized (178–183). Given recent warnings with use of LMWH after spinal surgery, clearance should be obtained from the spinal surgeon before initiating. Prophylaxis should be continued for persons with an AIS D injury while they are hospitalized. For those with motor incomplete AIS C or motor complete injury for 8 weeks, and for persons with motor complete injuries and other risk factors for 8 to 12 weeks (177).

Vena cava filter placement is recommended in patients who have failed anticoagulant prophylaxis, or who have a contraindication to anticoagulation. Routine placement of prophylactic caval filters is not warranted in all SCI patients (184). Filters should also be considered in individuals with high-level motor complete tetraplegia with poor cardiopulmonary reserve, patients with other high risk factors (i.e., long bone fractures), or with thrombosis of the inferior vena cava (IVC) despite anticoagulant prophylaxis. Filter placement is not a substitute for thromboprophylaxis, and may even be a risk factor for the development of a DVT. Treatment for a DVT or PE in SCI is similar to the non-SCI population and anticoagulation is usually continued for 6 months.

Chronically, DVT is seen less frequently; 2.1% at 1 year follow-up, 1% at 2 years, and 0.5% at 5 year follow-up (173), but still higher than the general population. Patients with complete injuries have a higher incidence. The consortium guidelines recommend prophylaxis in persons with chronic SCI who are hospitalized and require immobilization (177).

## PULMONARY SYSTEM

Respiratory failure is the leading cause of death in acute and chronic SCI (6,7,185,186). Approximately two thirds of all acute SCI patients will experience a complication of the pulmonary system including atelectasis, pneumonia, and/or respiratory failure requiring mechanical ventilation (187). The primary muscle for inspiration is the diaphragm, which receives its innervation from the phrenic nerve (C3-5), and contributes to 65% of the VC in able-bodied individuals. Additional muscles involved in inspiration include the external intercostals and accessory muscles including the scalenes, sternocleidomastoid, trapezius, and pectoralis. However, these alone are insufficient to maintain adequate oxygenation. Expiration is largely a passive activity caused by recoil of the chest wall. A forceful expiration, such as that required for effective cough, requires contraction of the abdominal and thoracic musculature, innervated by the thoracic level nerve roots (T1-11). The pattern of pulmonary dysfunction most commonly seen in SCI is one of restriction rather than obstruction.

The VC in the newly injured individual with tetraplegia is reduced but improves over time due to increased strength and the development of intercostal and abdominal tone that stabilizes the rib cage and enhances the mechanical effect of the diaphragm (188–190). The typical loss of VC in persons with a complete C5 motor lesion and above is roughly 50%; for C6-8 one third; and for T1-7 only slightly below the lower limits of normal (191–193).

Epidemiologic studies indicate that 20% to 25% of acutely injured SCI patients will require mechanical ventilation. Ventilation is usually initiated at lower tidal volumes (TVs) (6 to 8 cc/kg of ideal body weight) based on general ICU management, but many specialists in SCI suggest the volumes to be adjusted upward (10 to 20 cc/kg), while closely monitoring the patient pressures. Higher TV results in faster clearing of atelectasis and a better result in weaning off the ventilator (27,194,195). Oxygen should only be used as a temporary measure, as most patients have healthy lungs. If the oxygen saturation is low, the patient usually has secretions that need to be cleared or an insufficient TV.

Once patients are intubated, forced VC is a key parameter to follow. A VC of approximately 15 to 20 mg/kg is a good predictor of successful weaning from the ventilator (191). Patients with a neurologically complete NLI of C2 and above, will have no function of the diaphragm, and will need some type of ventilatory assistance immediately. While patients with injuries at the C4 or C5 level may initially require MV, most will be successfully weaned from the ventilator (196).

Weaning is usually attempted when the patient has a VC approximating 10 mL/kg body weight (195,197). The progressive free breathing technique is the recommended weaning protocol which consists of removing the patient from ventilator support with a gradual increase in time off the ventilator (186,198,199). This allows the patient to rest in-between trials, to gradually build up their strength, and to maintain expansion of the lungs in between the weaning trials. Other methods, including the use of noninvasive means of ventilation have been utilized. A peak cough flow of 160 L/min correlates with successful decannulation in persons with neuromuscular disease (200).

For patients who remain ventilator-dependent, direct stimulation of the phrenic nerves (phrenic nerve pacing) has been effective in facilitating ventilator weaning as well as improving speech and mobility (137,201,202). This method traditionally requires neurologically intact peripheral phrenic nerves (lesions above C2) that are stimulated via electrodes placed directly over the nerve, but intercostal nerve grafting for patients with phrenic nerve damage has been described (203). More recently, diaphragmatic pacing via electrodes placed intramuscularly over the phrenic nerve motor point has also been efficacious in ventilator weaning in persons with tetraplegia (204,205). Advantages of diaphragmatic pacing over phrenic nerve stimulation include laparoscopic approach versus the traditional thoracotomy required for placement of the phrenic nerve stimulators, as well as decreased risk of iatrogenic phrenic nerve damage (204,205). Noninvasive means of ventilation including intermittent positive pressure ventilation (IPPV) via mouthpiece, intermittent abdominal pressure ventilator, continuous positive airway pressure (CPAP), and biphasic PAP (BiPAP) can also be employed for persons with SCI.

Persons requiring MV have a high mortality rate, although greater numbers survive the initial injury. The 1-year survival for initially ventilated patients was approximately half of the 1-year survival for the total admissions to the model systems facilities (25.4% vs. 49.7%) (206). For patients who survive the first year on the ventilator, the 15-year survival rate is 61.4%. Survival of persons who are ventilator-dependent has improved during the first years after injury, but there is no evidence of improved long-term survival over the last few decades (207).

In the cervical and high thoracic level injured patients, the effective management of pulmonary secretions is critical. Manually assisted cough (i.e., “quad coughing”) is performed by providing an upward thrust on the abdomen while the patient attempts to exhale. Due to possible displacement of an IVC filter, it is best to not use “quad coughing” in patients who have a new IVC filter placed (208). Prior to performing a cough, secretions should be mobilized by percussion or use of devices similar to the “pneumovest” or “rocking bed,” which loosen secretions by gentle vibration to the chest wall. Routine tracheal suctioning can also be used to extract secretions, but one should observe for reflex bradycardia secondary to vagal stimulation. The use of a mechanical insufflation/exsufflation (MI-E) device is beneficial in managing secretions and can be

used via tracheostomy, face mask, or mouthpiece. The MI-E delivers a deep insufflation (positive pressure) to the airway that is immediately followed by an exsufflation (negative pressure). The rapid shift in pressure produces a high expiratory flow rate from the lungs, simulating a cough. Advantages of MI-E over suctioning include better ability to clear secretions from the left lung, larger mucous plugs can be removed, and is more comfortable and better tolerated by patients (209).

VC in tetraplegia is affected by the position of the patient, with a 15% decrease in the upright position relative to supine. The diaphragm, like other muscles, is at a mechanical disadvantage near its end range. In SCI patients with mid-thoracic level injuries and higher, the diaphragm tends to remain partially collapsed, placing it at a mechanical disadvantage and increasing the residual volume. An abdominal binder improves the respiratory function in the sitting position by placing the diaphragm in a more efficient position (210,211). The use of inspiratory resistance muscle training, abdominal weights, and incentive spirometry can improve pulmonary function (212). Glossopharyngeal breathing (GPB) is a technique that involves rapidly taking small gulps, 6 to 9 gulps of 60 to 200 mL each, and using the tongue and pharyngeal muscles to project the air past the glottis into the lungs. Many patients can use this technique to augment VC to assist with coughing or prolong ventilator free time (213).

Diseases of the respiratory system are the leading cause of death in chronic SCI, with the majority specifically due to pneumonia. Individuals with a history of ventilator usage at disease onset, a history of repeated atelectasis or pneumonia, a VC less than 2 L, nocturnal hypercapnea, or a mean SaO<sub>2</sub> less than 95% are at risk to develop late onset respiratory insufficiency. Immunization for pneumonia (every 5 years) and influenza (yearly) are important for persons with SCI as they are considered to be a high risk population (214).

## Sleep Apnea

Sleep apnea occurs in approximately 15% to 60% of patients with SCI (215,216). Common features include loud snoring, disrupted sleep, witnessed apnea, nocturnal gasping and choking, daytime sleepiness, and fatigue. It is commonly seen in older men with a short, thick neck, and tetraplegia. Certain medications (i.e., antispasticity and antiarrhythmics) and length of time from injury may also play a role. In SCI patients, the sleep apnea is primarily obstructive, with a small percentage of patients demonstrating central sleep apnea. Complications include daytime sleepiness and cognitive changes including poor attention, concentration, complex problem solving, short-term recall, and judgment. In addition, there is an increased risk for the development of hypertension, pulmonary hypertension, congestive heart failure, depression, and mortality.

It is advisable to review questions with the patient regarding sleep disturbance, snoring, and daytime somnolence. Optimal work-up would include an overnight oximetry recording, followed by a formal sleep study, if the oximetry recording is abnormal. Treatment includes assisted ventilation at night

and possible use of medications directed toward relief of upper airway symptoms.

## Orthostatic Hypotension

OH occurs when there is a decrease in systolic BP (SBP) by 20 mm Hg, or a decrease in diastolic blood pressure (DBP) of greater than 10 mm Hg or more (217). Many patients with acute SCI have a baseline SBP of 90 mm Hg or less, making symptoms a more reliable parameter to follow in diagnosis and treatment. SCI patients often experience symptomatic hypotension with position changes, especially moving from supine to more upright positions. Associated symptoms include lightheadedness, dizziness, ringing of the ears, fatigue, tachycardia, and sometimes syncope. In one study, OH occurred during 74% of therapy treatments in patients with acute SCI, with accompanying signs and symptoms noted on 59% of occasions, and were perceived as limiting treatment on 43% of occasions (218). OH can last for several weeks after the injury, delaying the rehabilitative process. OH occurs more frequently in persons with cervical level and neurologically complete injuries. When bed rest is prolonged, the degree of orthostasis tends to be more severe (219). OH intensifies after eating, exposure to warm environments, defecation, and rapid bladder emptying (220). Symptoms are related to a reduction in cerebral perfusion rather than a specific peripheral BP level.

Habituation to the symptoms of OH occurs slowly although the resting BP rarely returns to preinjury values, especially in person with tetraplegia. The exact mechanism is unknown, but theories include increased sensitivity of baroreceptors and catecholamine receptors in the vessel walls, development of spasticity, improved autoregulation of cerebral vascular perfusion, and adaptations of the renin-angiotensin system (221). Patients should be cautioned to avoid rapid changes in position. Simple adjustments, such as raising the head for several minutes prior to transferring out of bed, can be effective in decreasing episodes of OH.

Physical methods, including compression wraps to the legs and an abdominal binder donned prior to sitting up help to prevent venous distension and prolonged pooling of blood in the LEs, should be tried to mitigate orthostasis. Repeated postural changes on a tilt table or a high back reclining wheelchair also lessens the drop in BP. Maintaining adequate fluid intake is important and one should not be started on fluid restriction for an IC bladder program until the symptoms have improved. Avoiding diuretics such as alcohol and caffeine, and partaking in small meals to minimize postprandial hypotension are recommended. Sleeping with the bed head raised by 10 to 20 degrees should be encouraged to increase plasma volume and orthostatic tolerance.

Pharmacologic agents are added to the treatment regimen if the above interventions do not resolve the symptoms. Sodium chloride tablets (1 g four times per day), catecholamines such as midodrine hydrochloride (2.5 mg to 10 mg three times per day) are used; and if ineffective can initiate a salt-retaining mineralcorticoid such as fludrocortisone (0.05 to 0.1 mg daily) (222–224). The medication should be given approximately

1 hour prior to activity known to cause hypotensive episodes. Patients should be monitored closely for hypertension when taking these medications.

Chronic low resting BP may interfere with participation in activities that may provoke symptoms and impact QOL. Chronic hypotension may have a deleterious affect on the patient's long-term health, as low resting systolic BP (<110 mm Hg) is associated with fatigue and can lead to deficits in cognitive performance (225). These patients may also be at greatest risk for other cardiovascular abnormalities.

### Autonomic Dysreflexia

AD, also known as autonomic hyperreflexia, is a composite of symptoms, most notably a sudden rise in BP, is seen in SCI patients with injuries at or above T6, and is due to autonomic dysfunction. Individuals who are neurologically complete and at higher levels of injury are apt to have more severe symptoms (226,227). The incidence in susceptible patients varies between 48% and 90%, but rarely presents within the first month after injury, and nearly all patients who develop AD will do so within the first year (226–229).

AD is caused by a noxious stimulus below the level of injury. The most common source is from the bladder, either from over distension or infection, with the second most common source being the bowel (i.e., fecal impaction). These account for over 80% of all cases. Other causes include PUs, ingrown toenails, abdominal emergencies, fractures, and body positioning. In females, AD can occur during labor and delivery (230) and in males during stimulation techniques for ejaculation. The noxious stimulus travels via the peripheral nerves to the spinal cord and ascends in the spinothalamic tracts and dorsal columns where sympathetic neurons in the intermediolateral

cell columns are stimulated. Splanchnic vessels, which are innervated by nerves originating from T5-L2, constrict and raise the BP. The hypertension from AD is defined as a rise of 20 to 40 mm Hg above baseline (231). Symptoms include most commonly a headache that is pounding in nature and found in the frontal and occipital areas, followed by sweating and flushing above the level of lesion. Baroreceptors from the carotid sinus and aortic arch detect the elevated BP and relay impulses to the vasomotor center in the brainstem that attempts to compensate by slowing the heart rate via impulses through the vagus nerve. Signals meant to inhibit the sympathetic system are blocked at the spinal cord lesion (Fig. 27-4).

Signs and symptoms reflect sympathetic overflow, and the consequent compensatory reaction mediated by the PS nervous system. The sympathetic discharge causes hypertension and piloerection. The PS response causes headache, pupillary constriction, sinus congestion, and bradycardia. More serious and even life-threatening symptoms may occur including cardiac arrhythmias, seizures, intracranial hemorrhage, pulmonary edema, and myocardial infarction (232).

AD requires immediate attention, with the goal to remove the inciting stimulus and reduce the BP. The BP and pulse should be monitored every 2 to 5 minutes until stabilized. A rapid survey of the patient for the causes should be initiated. The first intervention upon diagnosis is to sit the patient upright with loosening of all tight fitting clothes. The bladder should next be checked for over distension by flushing an indwelling catheter if one is present or catheterizing the patient if without one. If the catheter is blocked, gentle irrigation with a small amount of fluid, at body temperature, is used. If available, xylocaine gel (2%) should be used prior to catheterization. If the bladder is the source, the BP should quickly

**FIGURE 27-4.** Autonomic dysreflexia.

return to baseline. If the pressure remains elevated (i.e., systolic BP > 150 mm Hg), pharmacological management should be initiated prior to checking for fecal impaction. If so, one should use an antihypertensive agent with rapid onset and short duration while the causes of AD are being investigated. Prior to rectal examination, xylocaine gel should be placed within the anorectal area. If impaction is not present, other possible sources should then be sought, including PUs, ingrown toenails, infections, fractures, DVT, and HO.

Medications used for AD most commonly include nitrate gels (e.g., nitroglycerine paste), and less frequently clonidine, nifedipine, terazosin,  $\beta$ -blockers, phenoxymethamine, and hydralazine. The use of nitrates is beneficial as they can be easily applied, titrated, and removed immediately if a source is later found. If using nifedipine, chew and swallow is the recommended route, rather than sublingual. The BP should be monitored frequently because hypotension may occur, especially if the source is found rapidly. The individual should be monitored for recurrent symptoms for at least 2 hours after resolution of the AD episode to ensure that it does not recur (231). If there is poor response to treatment and/or if the cause of the AD has not been identified, the patient should be hospitalized for monitoring, maintenance of pharmacologic control of BP, and investigation of other possible causes of the AD.

### Immobilization Hypercalcemia

After acute immobilization, calciuria increases within 2 weeks, reaching a maximum between 1 and 6 months after injury. The incidence of Hypercalcemia (level > 10.5) in SCI is 10% to 23%. Signs and symptoms usually present between 1 and 2 months postinjury, but may occur as early as 2 weeks and up to 6 months after injury. They can be vague and could include acute onset of nausea, vomiting, anorexia, lethargy, abdominal discomfort, constipation, diffuse musculoskeletal pain, polydipsia, and polyuria (which could result in dehydration). Risk factors include multiple fractures, younger age (<21 years) because of their high rate of bone turnover, male gender, high level lesion, complete neurologic injury, prolonged immobilization, and dehydration (233). Ingesting a high calcium diet does not increase either urinary or serum calcium concentration. For diagnosis, a serum calcium level should be evaluated, with correction for a low serum albumin if present. Ionized calcium can also be measured.

Treatment consists of IV fluid (normal saline at 100 to 150 cc/h), as tolerated, to increase the calcium excretion. A Foley catheter is recommended due to the volume of fluid being administered. Once the patient is hydrated, furosemide may be given to enhance calcium excretion, but often continued aggressive hydration alone is used. Calcium-sparing diuretics such as hydrochlorothiazide are contraindicated. Bisphosphonates such as pamidronate (30 to 90 mg IV administered over 4 to 24 hours) is effective, with the advantage of only requiring one dose, and has a rapid onset (234,235). This treatment rapidly lowers serum calcium within 3 days with the symptoms improving quickly as the serum calcium level drops. The serum calcium falls to a nadir within 7 days and

may remain normal for several weeks or longer. Some may require repeat treatment, so continued monitoring of calcium levels following treatment is recommended. Standing has been reported to decrease hypercalciuria (236,237). Other medications that have been used include calcitonin, etidronate, and glucocorticoids (2237,238). Treatment for asymptomatic hypercalcemia is recommended as prolonged hypercalcemia may cause nephrocalcinosis.

### GI Complications

Immediately after a SCI, an adynamic ileus is usually present and typically resolves within a week. Gastric decompression via nasogastric tube with intermittent suction may be necessary for persistent abdominal distention. Parenteral nutrition should be considered when the ileus lasts longer than 3 days. In cases where the ileus lasts longer, erythromycin and/or metoclopramide can be used to stimulate peristalsis (239). Neostigmine has also been effective in refractory cases of pseudo-obstruction (240).

Individuals with SCI have a higher risk of developing peptic ulcers compared with the general trauma population (241). The incidence is approximately 5% to 7%, although an incidence as high as 24% has been reported (242,243). Most ulcers occur acutely, within a few days from injury. Higher-level and more severe injuries (neurologically complete) have the greatest risk. The use of stress ulcer prophylaxis is recommended (histamine 2 blockers or proton pump inhibitors [PPI]) usually for 4 weeks unless other risk factors are present (24). PPIs are more effective in preventing upper GI bleeding in high risk patients; however, it may increase the rate of clostridium difficile infections.

Individuals with SCI have a higher risk (25% to 30%) of developing biliary stasis and gallstone disease compared to able-bodied persons (244,245). Impaired gallbladder motility has been implicated as the cause. Patients with lesions above T10 have impaired filling of the gallbladder and lower fasting volumes, which may make the bile more lithogenic. Due to altered sensation after SCI, the diagnosis may be more challenging. However, the majority of patients still presents with traditional symptoms, often with radiation of the pain to the right shoulder, and may still have findings such as right upper quadrant abdominal pain and tenderness (244,246). A high index of suspicion, as well as laboratory and radiographic tests are essential in making a timely diagnosis.

Superior mesenteric artery (SMA) syndrome is a condition where the third segment of the duodenum is compressed between the SMA and the aorta. It occurs rarely, though more commonly in persons with tetraplegia, with an incidence of less than 0.33%. The patient experiences nausea, vomiting, abdominal tightness, and bloating which is made worse after a meal or by lying supine. The diagnosis is made definitively with an upper GI series. Risk factors that may predispose patients to this condition include weight loss, use of a spinal orthotic, and immobilization in the supine position. Patients may gain some relief by lying on the left side and by taking metoclopramide (247).

Acute abdominal emergencies are often a challenge to diagnose, especially in patients with higher level SCI because of the absence of the usual signs and symptoms of abdominal pathology. It is, therefore, important to have a high suspicion in evaluating patients with SCI presenting with fever, abdominal pain, and/or pain radiating to the shoulders, and an elevated white blood cell count. Performing specialized lab tests, such as abdominal ultrasonography or CT scan early, is often helpful to confirm the diagnosis. Pancreatitis should be considered, especially in acute patients with unresolving ileus or recurrence of an adynamic ileus (248). The clinical recognition of acute pancreatitis is hampered by diminished or lost visceral sensitivity and therefore is based on laboratory investigations. Acute pancreatitis in the setting of high-level SCI may result from a combination of locally mediated sphincter of oddi dysfunction and vagal dominant innervation of the pancreatic gland in autonomic failure (249).

### Bowel Management after SCI

Full details regarding bowel management are discussed in Chapter 27. An effective bowel management program is important to both the physical and psychological well being of the SCI patient. More than one third of persons with paraplegia ranked the loss of bowel and bladder control as the most significant functional loss associated with injury (250). Stool incontinence can be devastating to patients, leading to social isolation, loss of income secondary to work absenteeism, depression, and decreased QOL (251–253). The goal is to establish an effective “bowel program,” a consistent and complete evacuation of the bowel at a specified time, in a relatively short time period, without incontinence between programs. The bowel program should be individualized for every patient and often requires trial and error. The level of injury, previous bowel habits, lifestyle of the patient, and availability of caregivers should be taken into account when planning a bowel program.

Bowel programs are ideally performed on a daily to every third day basis depending on the individual's desire or preinjury patterns. Sitting upright on a padded commode can facilitate a more natural position and is preferred to a side lying position. Key components of bowel management include the use of digital stimulation, dietary fiber intake, use of oral medications, and rectal evacuants. Fluid intake should be adequate to maintain soft stools and is recommended at 2 to 3 L/d, depending upon bladder management and restrictions.

The bowel program will vary depending on the type of neurogenic bowel dysfunction, that is, UMN versus LMN bowel. Patients with UMN injuries may have decreased GI motility, especially in the descending colon, but they will have normal to increased resting rectal tone and GI-related reflexes remain intact. These include the gastro-colic and recto-colic reflexes. To utilize the gastro-colic reflex (contraction of the colon occurring with gastric distension), patients should be instructed to perform their bowel program 20 to 30 minutes after eating. Caffeine may act as a stimulant and may be used prior to a bowel program to help facilitate fecal evacuation.

Dietary or supplemental fiber acts as a bulking agent and can enhance colonic transit time. It is suggested that the daily intake of fiber be at 30 g/d.

A bowel program for patients with UMN injuries is initiated—the “3-2-1” program consisting of a stool softener (i.e., docusate sodium) three times per day, two senakot tablets given 8 hours before the suppository, and one suppository started once bowel sounds are present. An integral part of the bowel program is digital stimulation which is performed by inserting a gloved lubricated finger into the rectum and slowly rotating the finger in a circular motion in a clockwise direction until relaxation of the bowel wall is felt or stool or flatus passes (approximately 1 minute). This initiates the recto-colic reflex; contraction of the colon occurring with stimulation of the rectal mucosa. This will trigger evacuation of stool in the lower rectal vault. Once the vault is empty, a suppository is inserted to stimulate contraction of the lower colon and evacuation of stool located higher in the descending colon. Repeat digital stimulation (three to five times) should be performed every 10 to 15 minutes to check for stool which may remain in the rectal vault until there is closure around the finger by the internal sphincter or there are no results after two stimulations. Ideally, the bowel program should be performed at the same time of day to facilitate “retraining” of the bowel. Patients injured for more than 1 year are more likely to perform the bowel program every other day, and in the morning. Persons with tetraplegia report requiring more assistance and more time overall for the program (254).

For patients who remain constipated, laxatives such as lactulose, polyethylene glycol, bisacodyl tablets, milk of magnesia, or cascara may replace, or be used in combination with components of the 3-2-1 program. The use of oral agents should be individualized, with the ultimate goal of minimizing medications as the time from injury increases. Only one change to the bowel program regimen should be at a time, and at least three bowel cycles should be completed to realize the effects of the change. While large volume enemas are occasionally indicated for episodes of constipation, they are not recommended for chronic use. Bisacodyl is an active ingredient in most suppository preparations. Suppositories with a water soluble base (Magic Bullet) have been shown to dissolve more quickly and significantly shorten the time to complete a bowel program compared with standard vegetable oil-based preparations (255). Docusate sodium mini-enemas may allow for the most rapid bowel evacuation (256).

Surgical interventions should be considered if diet modifications, medications, and physical techniques have been attempted but fail to produce a consistent bowel movement. Colostomies and ileostomies decrease the time required for bowel management, increase independence, and simplify the overall process. Many patients have reported that they retrospectively wished that these alternatives were offered earlier (257,258). An antegrade continence enema (ACE) procedure may be an option for adult patients with neurogenic bowel recalcitrant to a bowel program. Originally designed for children with myelomeningocele, it also significantly decreases toileting time and improves QOL (259). Patients also find

it more cosmetically acceptable than a colostomy. Recently, studies examining a transanal irrigation system have shown improvements in constipation, QOL measures, and fecal incontinence (260).

In LMN lesions, continence is often lost due to weakness of the pelvic floor muscles with a flaccid external anal sphincter. Because spinal-mediated reflexes are absent, digital stimulation and contact irritant suppositories are largely ineffective, necessitating manual disimpaction. The stool is kept firm by use of bulking agents to aid manual disimpaction. Performing the disimpaction more than once per day may be required. Assistive techniques such as valsalva maneuver, abdominal massage in a clockwise direction starting in the right lower quadrant and progressing along the course of the colon, increase in physical activity, standing, and completing the bowel program in a commode chair rather than in bed can also greatly facilitate the process.

## GU SYSTEM

Prior to the 1970s, renal disease was the leading cause of mortality in chronic SCI. Since the advent of IC programs, the prevalence of renal disease has decreased dramatically. Acutely, patients are usually in spinal shock, with the bladder being areflexic, retaining urine. This can last from a week to 1 year, but in most cases resolves after 6 to 12 weeks. An indwelling catheter is the initial management of choice to remove urine and monitor output. Patients can be started on an IC program, when they can tolerate a fluid restriction of approximately 2 L/d. Once patients are medically stable, a discussion regarding the long-term management options should commence. The goal is to have a “balanced bladder” that includes maintaining low bladder pressures and continence while minimizing infections and the risk of upper tract deterioration (261,262). As with the prescription of the bowel program, patient preference must be considered. Ideally, the clinician will present all available management strategies, including pros and cons of each, and the ultimate decision will be made by the patient.

For patients with an UMN injury who have adequate hand function, an IC program provides a near physiologic voiding pattern. For patients who have urinary leakage between catheterizations, or high filling pressures documented on urodynamics, anticholinergic medications can be administered. Newer techniques, including botulinum toxin to the detrusor wall, are being used. Volumes of each IC should be less than 500 cc and frequency of caths are most feasible four to five times per day; correlating with a 2 to 2.5 L fluid restriction. Patients must understand that failure to comply with the catheterization schedule may lead to high bladder volumes and pressures, and ultimately may progress to upper tract deterioration. The benefits of an IC program include improved self-image and conduciveness to sexual activity, and it may result in a decreased incidence of bladder stones, UTIs, and bladder cancer. IC is generally accepted to be the best and safest long-term bladder method.

Chronic indwelling catheters (i.e., urethral and suprapubic) are generally easy for patients and caregivers to manage. Negative consequences associated with indwelling catheters include increased incidence of bladder stones, UTI, urethritis, urethral erosions, prostatitis, strictures, and cancer for long-term (more than 10 years) users. Additionally, the presence of the catheter may hinder attempts at intimacy. However, when other more medically appropriate methods are not functionally feasible, this type of option is preferred (261).

Reflex voiding (with a condom catheter) is an option for men with UMN bladders, but urodynamic monitoring is recommended to assure voiding at acceptable pressures. There are no consistent external catheters for women. Careful monitoring of postvoid residuals is needed to insure adequate emptying as urinary stasis increases occurrence of UTIs. If there is an outlet obstruction, the use of  $\alpha$ -blockers, botulinum toxin injection of the external urethral sphincter, and surgical procedures are available. In addition, there are a number of surgical approaches to assist in bladder management for the patient with chronic SCI. These include FES techniques, and approaches for continent and incontinent diversions (261,262).

For patients who have a LMN bladder, techniques such as Crede (direct pressure applied over the lower abdomen) and/or valsalva maneuvers may provide enough pressure to cause expulsion of urine from the bladder. Patients should be cautioned that this method can increase bladder pressures thereby increasing the risk of hydronephrosis. For this reason, these maneuvers are not advised for patients with known dyssynergia. IC programs are otherwise the best option.

Patients with neurogenic bladder dysfunction require routine screening for development of stones, fibrosis, hydronephrosis, renal disease, and bladder cancer (261). The presence of bacteria in patients with indwelling catheters or who perform IC is quite common. A UTI is defined as: (a) significant bacteriuria, (b) pyuria, (c) clinical signs and symptoms, for example, fever, malaise, increased spasticity, or neurogenic pain (263). Generally, asymptomatic bacteriuria is not treated and the use of prophylactic antibiotics to prevent UTIs after SCI is not supported (264). Exceptions include patient who are scheduled to undergo invasive procedures such as cystoscopy or urodynamic studies, or have urease-producing pathogens (e.g., proteus, pseudomonas, Klebsiella, Providentia, *E. coli*, *Staphylococcus epidermis*), or in the presence of reflux.

Follow-up screenings are recommended, although the frequencies of these are variable across SCI centers. Renal sonograms are generally obtained every 1 to 2 years, or if there is clinical evidence suggestive of nephrolithiasis. Patients with indwelling catheters should have regularly scheduled cystoscopy evaluations at least every 2 to 3 years to screen for bladder cancer. Those at higher risk, that is, smokers, those with a history of abnormal cystoscopy findings, require more frequent examinations. Patients with persistent hematuria or constitutional symptoms consistent with an underlying malignancy should be screened immediately. Urodynamic studies are indicated whenever there is a change in the patient's voiding pattern.

and for occasional screening to assure appropriate filling and voiding pressures.

The incidence of renal calculi in SCI is approximately 5% to 10% (173). Stones are typically associated with UTIs, especially with bacteria that are urease-producing, since urease alkalizes the urine and promotes crystallization of struvite and calcium phosphate stones. The most common stones previously reported are infection-related stones with struvite (magnesium ammonium phosphate), followed by calcium oxalate and phosphate stones; although this trend may be changing (265). Risk factors include the presence of ureterovesicular reflux, chronic UTIs, higher level and more complete injury, indwelling catheterization, and bladder stones (266,267). Staghorn calculi are more common with struvite stones and carry a higher morbidity rate.

Clinical presentation of renal stones includes flank pain, nausea, emesis, hematuria, hyperhydrosis, presence of AD, or recurrent UTIs. Workup includes stone analysis once obtained, with serum studies (BUN, creatinine, calcium, and phosphorus); urinalysis (including urine pH); and a 24-hour urine for total volume and measuring calcium, oxalate, citrate, magnesium, uric acid, sodium, potassium, and phosphorus. Imaging such as a KUB x-ray, which can visualize calcium stones (struvite stones are not as dense), ultrasound, computerized axial tomography (CAT) scan, and intravenous pyelography (IVP) may be used. Treatment for kidney stones includes medical stabilization with fluids, treatment of infection if present, and pain management. Surgical treatment for stones includes extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy, ureteroscopy, and open nephrolithotomy. Once stones are present, there is a recurrence rate of 15% to 72% over a 5-year-period. (For more information on neurogenic bladder dysfunction, see Chapter 24.)

### Osteoporosis

Following injury, there is a marked increase in osteoclastic activity leading to net bone resorption. Bone loss is most active in the first 14 months postinjury, with a slower loss over the next few years, placing patients at an increased risk early after injury of developing pathological fractures (268,269). Bone loss occurs in the LEs at a rate of 1% to 2% per month, with a more rapid loss in the distal femur and proximal tibia as compared with the proximal and midshaft femur. There is a greater loss of trabecular bone as opposed to cortical bone. There is also loss of bone mass in the UE of persons with tetraplegia, with reported normal to an increase in bone mass in the lumbar spine of all patients, possibly due to constant loading while sitting in the wheelchair, and in the forearm of athletes. The increase in the lumbar spine bone mass may just represent a spurious finding rather than being spared bone mineral loss (270). There is no difference in bone loss in the LEs between persons with paraplegia or tetraplegia (269,271). The greatest risk factors for osteoporosis, especially at the knee, include a neurologically complete injury, lower body mass index (BMI), and greater age.

Most patients with chronic SCI have T-scores on DEXA scan of the LEs of greater than 2 standard deviations below the

mean, and therefore this value alone cannot determine fracture risk. In addition, the sites of measurement are not always consistent with the sites of fracture most common in SCI. Garland et al. reported that patients who experience pathologic fractures of their LEs have lost 50% of the BMD of their knees (relative to able-bodied group) and that the fracture threshold of the knee is 0.6 g/cm<sup>2</sup> (272). A study utilizing quantitative CT that calculates volumetric densities reported a fracture threshold of approximately 110 mg/cm<sup>3</sup> in the distal femur and 70 mg/cm<sup>3</sup> in the distal tibia (273). Below these levels, fracture due to minor trauma is common.

Treatments for bone loss have included weight bearing, FES, and pharmacological intervention (274). Therapeutic interventions including the use of standing tables, ambulation, and FES have produced mixed results (275–278). While there may be a dose-response effect in utilizing FES, the precise requirements needed to obtain clinically useful outcomes are yet to be determined. The use of FES in a person with chronic SCI and low BMD may lead to fracture, and caution should be taken (279). Possible treatments to prevent bone loss following SCI including the use of bisphosphonates, is being researched. Data have shown promising results in decreasing bone loss in the acute injury period; however, sustained benefit postinjury and its effectiveness on long-term fracture rates are unclear (280–282).

### Fracture

The historical incidence of long-bone fractures ranges between 2% and 6%, and has been documented at approximately 2.5% over 20 years after SCI in model SCI system data (173). The incidence is most likely much higher when one considers that many individuals with SCI have impaired sensation, and thus may not seek medical treatment. Fractures are more common in women and persons with neurological complete injuries, and in paraplegia relative to tetraplegia (272,283). Most fractures are due to falls during transfers, but fractures can result from minor stresses (e.g., long-sitting or ROM) or without any known etiology. Supracondylar femur fractures are the most common fractures, followed by the distal tibia, proximal tibia, femoral shaft, femoral neck, and humerus, respectively. A bone mineral density fracture threshold of 50% appears to exist for the knee, and this most likely is the bone mineral density fracture threshold for most regions in the body. Symptoms of acute fracture include fever, acute pain, swelling, or increased spasticity. A plain x-ray will usually give a definitive diagnosis.

For fractures in chronic patients with SCI who do not use their lower limbs for functional mobility, the main goals of treatment are to minimize complications, allow for healing with satisfactory alignment, and to preserve prefracture function. Most fractures are treated nonoperatively with soft padded splints (284,289). A well-padded knee-immobilizer is useful for femoral supracondylar, femoral shaft, and proximal tibial fractures; a well-padded ankle immobilizer can be used for distal tibial fractures. In nonambulatory patients, some degree of shortening and angulation is acceptable. The patient should be allowed to sit within a few days. Callus formation is

usually evident in 3 to 4 weeks; however, ROM is initiated at 6 to 8 weeks, with weight bearing delayed for a longer period. While nonunion of fractures occur (2% to 10%), this is not clinically significant in those who do not weight-bear through their lower limbs.

Surgery, circumferential casting, and external fixation are usually not indicated in the SCI population because of potential complications due to low bone mass, risk of osteomyelitis, recurrent bacteremia, and skin breakdown. Surgery may be indicated when conservative methods will not control rotational deformity, for proximal femur fractures, in patients with severe muscle spasm, if vascular supply is in danger, and in whom shortening and angulation will result in unacceptable function or cosmesis. Femoral neck and subtrochanteric fractures are the most difficult to manage and internal fixation may be considered if a minimal device such as an intramedullary rod can be used.

### Heterotopic Ossification

HO is the formation of lamellar bone within the soft tissue surrounding a joint. The incidence ranges between 13% and 57%, and is usually found in the first 6 months (peak at 2 months) after injury. HO may occur beyond 1 year and is usually associated with a newly developed PU, DVT, or fracture. Risk factors for HO include older age (children and adolescents have a lower incidence), neurological complete lesions, male gender, spasticity, DVT, and pressure sores (285,286). These risk factors may be cumulative.

Most of the cases of HO will have only radiological findings and are not clinically significant. Up to 20% will present with a limitation of the ROM, with up to 8% progressing to joint ankylosis. Only joints below the NLI will develop heterotopic bone, with the most common location being the hips (anteromedial aspect), followed by the knees, then shoulders. The joint may appear warm and swollen and must therefore be differentiated from a septic joint, cellulitis, DVT, fractures, and inflammatory arthritis. The patient may experience pain, malaise, low-grade fever, and an increase in spasticity. In severe cases, adjacent neurovascular structures may be compromised leading to distal extremity swelling and nerve entrapment (287).

The pathogenesis of HO is not fully understood, but involves changes of soft tissue mesenchymal cells to osteogenic precursor cells by humeral, neural, and local factors. Bone morphogenic protein is thought to play a key role (288). Damage to the sympathetic tracts in the spinal cord may also promote HO by increasing the local vascularity and blood perfusion around the joint. When passive ROM is delayed more than 1 week after injury, patients are more likely to develop HO (289). It is also possible that forced ROM of contracted limbs may cause micro trauma and bleeding, leading to HO (290).

Laboratory tests are sensitive but are not specific markers for HO. Serum alkaline phosphatase levels start to increase prior to clinical and radiographic presentation, but may not exceed normal levels for several weeks. Because levels do not correlate with the amount or degree of bone activity, they

should not be used to judge the maturity of the new bone or predict its recurrence. An elevation of serum creatinine phosphokinase (CPK) may be a more reliable predictor of HO (291,292). While nonspecific markers of inflammation such as C-reactive protein (CRP) and the erythrocyte sedimentation rate (ESR) can be useful in following disease activity (293), any cause of systemic inflammation (e.g., infection, PUs) may result in these elevations. CRP is a more reliable predictor of disease activity, with normalization of the CRP correlating with resolution of the inflammatory phase of HO. Urinary excretion of hydroxyproline and collagen metabolites correlates with alkaline phosphatase levels and can also serve as indirect markers for the presence of HO.

A triple phase bone scan is the most sensitive imaging study in diagnosing early HO, and can detect disease activity before calcification becomes apparent on plain x-ray. The first two phases of the bone scan measures the increase in blood flow to a joint during the early inflammatory period. The third phase, or static bone phase, is more specific since it measures the incorporation of the radionuclide into the bony matrix but may take another 3 weeks before it is positive (294). Bone scans are also the most useful technique to assess maturity of the heterotopic bone. Plain x-rays become positive approximately 2 to 6 weeks after a triple phase bone scan first reveals HO or 1 to 10 weeks after clinical presentation (295). Ultrasonography may be positive early and has the advantage of being a relatively inexpensive examination without requiring radiation (296). MRI, with an increased T2 signal (edema) in muscles, fascia, and subcutaneous tissue can be helpful in diagnosing HO acutely (297). CT scan may be used to determine the volume of bone needed for planning surgical resection. Multiple grading systems for classifying HO have been proposed (285).

Treatments include ROM with gentle stretching after the acute inflammatory period is over (1 to 2 weeks), bisphosphonates, NSAIDs (e.g., indomethacin) if not contraindicated, radiation therapy, and surgical excision (298). Passive and active assistive ROM to the affected limb is necessary to prevent further loss of ROM. Aggressive ROM (beyond the initial end-point), especially during the acute inflammatory phase, is not recommended (299). Treatment with bisphosphonates has been shown to decrease the rate of new bone formation in patients with HO; however, it has no effect on bone which has already been deposited. Disodium etidronate inhibits osteoclastic activity and conversion of calcium phosphate to hydroxyapatite. Although IV administration of etidronate reportedly led to quicker resolution of edema with less rebound formation after the medication was discontinued, it is no longer available. Current recommendation is for oral administration of etidronate 20 mg/kg/d for 6 months if the CPK level is elevated at the time of diagnosis or 20 mg/kg/d for 3 months, followed by 10 mg/kg/d for an additional 3 months if the initial CPK level is normal (300). With this regimen, there was faster resolution of edema with less rebound formation after the medication was discontinued. If CPK is elevated, or CRP greater than 8, some recommend addition of a NSAID until

the CRP less than 2 or CPK normalizes. Clinical trials with newer generation bisphosphonates are ongoing.

Surgical excision should be reserved for patients with severely limited ROM that causes functional limitations. Most clinicians recommend waiting until after the ectopic bone is mature by bone scan, which may take up to 12 to 18 months to occur. Complications of surgery include significant blood loss, infection, and recurrent HO. Postop treatment includes NSAIDs for at least 6 weeks, bisphosphonates for 3 to 12 months, and/or radiation. While radiation decreases the degree of recurrence of HO, complications include delayed wound healing, osteonecrosis, and the risk of developing sarcoma (295,301).

Prophylaxis of HO in SCI patients has been studied using several agents including etidronate and indomethacin (75 mg daily for 3 weeks within 5 weeks of injury), with less HO formation as compared with placebo (302,303). Warfarin may also be an effective agent by inhibiting the formation of osteocalcin (304). Despite the available therapeutic options, prophylaxis is still not routinely used because of the relatively low incidence of morbidity (286,295,305).

### Thermoregulation

When the core temperature is cool and requires an adjustment, the hypothalamus, which regulates body temperature, employs shivering and vasoconstriction to increase temperature. Similarly, sweating and vasodilatation decreases temperature through increased heat loss. After a SCI above the T6 level, the ability of the hypothalamus to direct the periphery is impaired. This results in the patients being partially poikilothermic, in that they may have difficulty maintaining a normal core temperature in response to environmental change in temperature (306,307). This is an important factor to keep in mind when a person with SCI has a high temperature while in a warm environment. In addition, patients should be cautioned to wear appropriate clothing depending on the setting/environment they are in. Patients with chronic tetraplegia also frequently have subnormal body temperatures (<97.7°F) in a normal ambient environment (308).

### Anemia

Anemia is a common finding following acute SCI, and is usually normochromic and normocytic (309). Serum iron, TIBC, and transferrin are usually low. Although the exact cause is not known, bleeding may be a factor in some cases. By 1 year postinjury, anemia improves in the majority of patients and if it persists it is usually associated with chronic inflammatory complications such as PUs or frequent UTIs (310).

### Pressure Ulcers

PUs are one of the most common and potentially serious complications of SCI (see Chapter 23). Model system data reported that since 1996 approximately 24% of patients developed at least 1 PU during their initial rehabilitation (172). This is a decrease from previous studies that reported a prevalence of approximately one third of patients who developed a PU during their initial hospitalization and rehabilitation (172,

**TABLE 27.10 NPUAP Staging of PUs**

Stage	Description
I	Non-blanchable erythema of a localized area usually over a bony prominence.
II	Partial-thickness loss of dermis or dry shallow ulcer.
III	Full-thickness destruction through dermis into subcutaneous tissue. Subcutaneous fat may be visible but bone, tendon, or muscle is not exposed. May include undermining and tunneling.
IV	Full-thickness tissue loss with exposed bone, tendon, or muscle.

Deep tissue injury.

Unstageable wounds.

Source: NPUAP new revisions. Available at: <http://www.npuap.org/pr2.htm>.

311–313), with a lower incidence for persons admitted immediately to a model SCI center. The longer time injured, the greater the risk of developing an ulcer, as up to 80% of persons with SCI develop a PU at some point in their lifetime, with a community prevalence of approximately one third (175,314–316). Skin issues are the second most common etiology for rehospitalization in chronic SCI (327). Persons with AIS A, B, or C paraplegia are more likely to be rehospitalized with skin issues than those with any level of tetraplegia or AIS D paraplegia.

PUs are classified using the National Pressure Ulcer Advisory Panel (NPUAP) staging system, with new revisions as of 2007 (317) (Table 27-10). The NPUAP includes the original four stages (318) and additional two categories on deep tissue injury and unstageable PUs. Staging should only be used when the wound bed can be visualized. Deep tissue injury refers to a purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. Unstageable wounds occur when not enough slough and/or eschar is removed to expose the base of the wound, and therefore the true depth cannot be determined and therefore staged.

PUs develop over bony prominences. The most common location in persons with SCI within the first 2 years is the sacrum, followed by the ischium, heels, and trochanters. After 2 years, the ITs are the most common site of development. In children up to age 13 years, the occiput is the site of most frequent development.

The most important risk factors for the development of PUs are pressure and shear. Other risk factors significant in SCI include level and severity of the injury, mobility status, gender, ethnicity, marital status, employment status, educational achievement, tobacco and alcohol use, history of a prior PU, nutritional status, anemia, incontinence, smoking, and possibly psychosocial issues (i.e., depression).

Secondary effects of PUs include further medical morbidity, pain (especially in incomplete lesions), increased spasticity, and wound infections. In addition, psychological complications from prolonged bed rest (often required for management of the sore) often occur, along with a diminished QOL secondary to

decreased recreational and vocational activities and a significant burden financially. Costs can be staggering in terms of lost workdays, increased attendant or skilled care, specialized bedding, supplies, hospitalization, and surgery (319). Previous estimates of costs (1990s costs) range from \$20 to 30,000 for less serious ulcers to \$70,000 to heal a full thickness ulcer (313). These do not take into account all of the hospital and postoperative costs as well as the indirect costs of the ulcer.

PU prevention is critical, and education regarding this should begin as early as possible after injury. This includes continued observation of skin (teaching patients to use a mirror), avoidance of excessive pressure or shearing, proper turning frequency in bed and weight relief techniques when seated, proper equipment (e.g., mattress, wheelchairs, cushions, and seating system), and early recognition and treatment. In addition, maintaining proper nutrition and discontinuing smoking are recommendations that will help prevent and heal ulcers if they develop.

The key to treatment of PUs is to relieve the pressure. Pressure mapping can be helpful in establishing an appropriate seating system for the patient to assure that appropriate pressure distribution occurs while sitting, and that appropriate weight relief is produced during the pressure reliefs. There are a great deal of dressings, gels, and ointments available on the market, but the most important aspect is to remove the etiology (e.g., sitting for prolonged periods in cases of an ischial wound). Wound management is discussed in Chapter 23. A VAC<sup>R</sup> system, a controlled application of sub-atmospheric pressure to the wound, can be used to keep the wound clean and help promote wound healing (313). Surgical consultation should be considered in most cases of stage 3 and 4 wounds for potential surgical intervention. There are a number of surgical options available (see Chapter 23 for details) but it should be recognized that surgery does not treat the underlying cause of the ulcer. Postoperatively, this still needs to be addressed. An appropriate sitting program should be followed after these procedures.

### Dual Diagnosis: TBI in Person with SCI

The incidence of concomitant TBI in those with a primary SCI is reported between 24% and 60% (320,321). Historical factors such as mechanism of injury (i.e., high velocity impact), loss of consciousness, prolonged extrication and/or intubation at the scene, higher NLI, presence of PTA, and impaired initial Glasgow Coma Scale (GCS) score, should alert medical personnel of the possibility of a concomitant TBI.

The individual with a dual diagnosis presents a challenge to the rehabilitation team (322). Deficits may be seen in attention, concentration, and memory as well as interfere with new learning and problem solving. The patient may exhibit agitation, aggression, disinhibition, and depression. This is problematic as SCI rehabilitation requires intensive new learning, with the ability to master new skills in terms of mobility and self-care, and adapt to a new lifestyle to be able to integrate into the community. Recognizing that the TBI exists and then developing a comprehensive treatment program to deal with the dual injury is necessary in order for the individual to meet their maximum potential. Before a patient is diagnosed as having a dual disability

based on behavioral issues, the clinician should seek other causes for such behavior including the possibility of seizures, post traumatic hydrocephalus, intracranial pathology, neuroendocrine disturbance, metabolic disturbance, side effects of centrally acting medications, hypoxemia, and infectious issues.

Medical management of problems common to the SCI population such as pain, DVT prophylaxis, spasticity, and neurogenic bladder requires special consideration in the dual diagnosis patient. In addition, the physician needs to take into account some medications routinely used in SCI that may have an impact on the recovering brain (i.e., baclofen and benzodiazepines). Special care should be taken to utilize medications with minimal cognitive impact. Peripherally acting medicines are generally preferred to those with central mechanisms of action. Clinical findings in SCI individuals may have different etiologies and as such require different treatments in the patient with dual diagnosis. Fever may represent infection, poikilothermia, or “central fever” which occurs in TBI. Once the former two etiologies have been excluded, treatment with a  $\beta$ -blocker can be considered. Elevated BP may signal the presence of AD in those with SCI at or above the T6 level. However, those with concomitant TBI may experience transient elevation of BP secondary to a centrally driven “sympathetic storm.” If initial interventions to treat AD do not improve the patient’s BP, pharmacotherapy should be initiated. Agitation is common in those with TBI and should be managed similarly in those with dual diagnosis. Behavioral interventions such as redirection and decreasing environmental stimulation are first-line treatments. Pharmacotherapy is appropriate when behavioral modifications are ineffective.

In those with TBI, acquisition of new information is often challenging, and may benefit from simple task repetition in therapy until individual skills can be completed with minimal prompting from the therapist. The therapeutic environment itself may also differ, as persons with TBI may perform better in less stimulating environments (i.e., with fewer visual and auditory distractions, with close supervision by the treating therapist). Cognitive therapy strategies should be reinforced by all members of the treating team such as reminding patients to utilize memory books and orientation cues with each clinical encounter. Neuropsychological evaluation is extremely important.

While few studies have examined the effects of TBI on outcome among individuals with SCI, greater adjustment difficulties and unmet needs were noted among persons with dual diagnosis (323–325). Smaller functional gains (as measured by the motor FIM) in those with dual diagnosis have been reported, however, no significant difference in rehabilitation LOS has been observed (326). Medical morbidities may be increased. For example, there could be an increased risk of PU due to the inability of the patient to remember to perform a pressure relief, and bladder and bowel difficulties due to the inability to perform these programs adequately.

### Spasticity

The incidence of spasticity in UMN-related SCI is approximately 70%, with roughly half the patients requiring

pharmacological intervention (327,328). While spasticity may occasionally contribute to improved function (i.e., transfers, standing, ambulation, and assisting in ADL), it more often leads to various complications including contractures, pain, impaired function, and decreased QOL. Spasticity occurs more frequently in persons with cervical and upper thoracic SCI than in those with lower thoracic and lumbosacral SCI, and is usually more significant in persons with certain incomplete injuries, AIS grades B and C, than in persons with grades A or D. Details regarding the basic definitions of spasticity, diagnostic procedures, and treatment options, are in Chapter 60.

Clinical examination is important, however, the degree of spasticity may vary during the course of the day. Therefore, the patient's description of secondary problems from spasticity becomes extremely important in determining whether to treat. The most common clinical scales used to assess spasticity in SCI include the Ashworth scale (AS) (329), modified Ashworth scale (MAS) (330), the Penn spasm frequency scale (PSFS) (331), Spinal Cord Assessment Tool for Spasticity (SCATS) (332), visual analog scale (VAS), self-rated scale of spasticity (333), and the Wartenberg Pendulum Test (334). Different scales measure different aspects of spasticity and individual tools correlate weakly with each other (335).

Before initiating treatment, potential nociceptive sources should be evaluated and if present, they should be treated. Common causes include UTI, bladder calculi, PUs, abdominal pathology, ingrown toenails, hemorrhoids, and bowel impaction. Selective serotonin reuptake inhibitors (SSRIs) have been reported to increase spasticity (336). Changes in spasticity in an otherwise stable patient may also be an important presenting sign in syringomyelia (337). Spasticity-related interventions should be aimed at what matters most to the patient, improving comfort and function, and allowing the individual to participate in life activities.

Stretching is a mainstay of treatment for SCI-related spasticity (338) and should be done twice a day or more. Standing activities, including use of tilt table or standing frame, provide prolonged stretch to joints and may reduce spasticity as well. Modalities have been used including cold and ES, usually with short-term benefits. Posture and positioning are extremely important for tone reduction. Adequate low back support in the wheelchair to maintain lumbar lordosis and a positive seat plane angle or "dump," with a reduction in seat-to-back angle, encourages proper upright posture and may reduce extensor tone. Inhibitive casting, splinting, and orthotic management of muscles and joints at risk for contracture may be helpful in reducing tone (338,339).

There are numerous medications for persons with SCI-related spasticity. A systematic review indicated that there is insufficient evidence to assist clinicians in a rational approach to antispasticity treatment in SCI (340), and therefore some amount of trial-and-error is required. The person's age, comorbidities, and cognitive status should be carefully considered when choosing a medication for spasticity.

Baclofen exerts GABA agonist activity by binding presynaptically at the GABA B receptor. The dosage of baclofen used in SCI is often higher than that described in the Physician

Desk Reference (PDR) (341). If baclofen is to be discontinued, it should be tapered as abrupt discontinuation can result in seizures, visual disturbances, and hallucinations. Benzodiazepines may affect cognitive performance measures such as attention, concentration, and memory, and are generally not used in persons with concomitant brain injury. A single night-time dose of diazepam or clonazepam is often used to treat nocturnal spasms that interfere with sleep. Alpha 2 adrenergic agonists, including clonidine and tizanidine, bind to presynaptic  $\alpha$ -2 receptors on interneurons in the dorsal horn of the spinal cord, resulting in depression of polysynaptic reflexes. Clonidine can be delivered either orally, via transdermal patch, or intrathecally (342,343). Tizanidine has a shorter half-life and lower incidence of hypotension than clonidine, and has been shown to be effective in patients with SCI and MS (344,345).

Gabapentin (especially at higher doses of >1,800 mg/d) and pregabalin, both anticonvulsants, have antispasticity benefits in persons with SCI (346–348). Dantrolene sodium prevents the release of calcium ions from the sarcoplasmic reticulum along muscle fibers, and acts on normal as well as spastic muscle, potentially resulting in weakness. Dantrolene may be of special benefit in persons with concurrent SCI and TBI, since its effects are peripheral rather than in the central nervous system (349). The most worrisome side effect is hepatotoxicity that occurs in approximately 1.8% of patients. Cyproheptadine is a nonselective serotonergic (5-HT) antagonist, which has antihistamine quality, and reduces clonus and spontaneous spasms in patients with SCI either alone (350) or in combination with clonidine (351). Most common side effects include fatigue and excessive weight gain. Opiates exhibit potent antispasticity activity (352) by suppressing polysynaptic reflexes to a greater extent than monosynaptic reflexes, but are not considered a primary treatment option for SCI-related spasticity. Four-aminopyridine (4-AP), a potassium channel blocking agent has shown some effect on decreasing spasticity and improving function in persons with incomplete SCI (353). Although not approved for clinical use, cannabis has been beneficial for persons with SCI-related spasticity (354).

Intrathecal baclofen (ITB) is of benefit for persons with SCI, with effective control of spasticity in the lower limbs being greater than in the trunk and upper limbs (355). Intrathecal clonidine may also be effective either alone (356) or in combination with baclofen (357), although this is not FDA approved. Careful patient selection is critical with close monitoring for pump failure or other complications.

Peripheral nerve and motor point blocks with alcohol or phenol allow for a focused delivery of drug to manage focal areas of spasticity. These drugs can have effects of up to 1 year by causing destruction of the axons. Botulinum toxin, which can be injected into the affected muscle, blocks neuromuscular transmission by inhibiting the release of acetylcholine into the synapse. It has an onset of action of 4 to 10 days, the effect lasts on an average for 3 months, and it has shown efficacy in improving UE and LE functions (358,359). Follow-up stretching, which may include dynamic splinting or serial casting, is recommended to optimize function.

Surgical interventions, including corpectomy and myelotomy, have been performed to reduce spasticity, but with limited long-term success (360). More selective procedures, dorsal rhizotomy, and dorsal root entry zone (DREZ) procedures, have been proposed to control spasticity by decreasing the afferent component of spasticity, although these should only be considered if all previous treatments have failed.

## PAIN AFTER SCI

Pain after SCI is common enough to be considered an expected condition (361). In the acute phase, pain is usually related to damage to the soft tissue and skeletal system from the initial trauma. After the injuries are appropriately treated, this type of pain usually subsides. However, between 47% and 96% of patients will develop pain thereafter (362–366). Model system data indicate that pain prevalence is up to 81% at 1 year after injury and 82.7% at 25 years. Pain is rated as severe in 20% to 33% of persons with pain after SCI. The presence of chronic pain is a significant contributor to decreased QOL, lower levels of psychological functioning and social integration, and an increased interference with ADL (367). The impact of pain on QOL may be greater than that of the injury itself (368).

Despite numerous classifications proposed, there is no single widely accepted scheme for SCI pain. Three main classifications include the International Association for the Study of Pain (IASP) (369), Bryce-Ragnarsson (370), and Cardenas classifications (371). Most share two basic categories of pain after SCI: musculoskeletal/nociceptive and neuropathic/neurologic. As a major category, musculoskeletal pain is more common, occurring in 50% to 60% with SCI greater than 5 years, while neuropathic being prevalent in 30% to 40% of persons 5 or more years after SCI. Although the classifications are similar in some ways there are differences in the organization, level of detail, and terminology used for particular types of pain. As none have achieved universal acceptance, a joint initiative between ASIA and ISCOS is developing a universally accepted assessment tool for pain in SCI.

Musculoskeletal pain refers to the pain originating from damage to tissue and bone structures and may include overuse syndromes, fractures, and compression syndromes. Neuropathic pain (also called neurologic or central pain) is directly attributable to spinal cord damage and can be divided into multiple subtypes by the level of injury (at the zone of injury or below) and etiology. It is often described as burning, tingling, cramping, shock-like, or a sensation of intolerable coldness. Neuropathic pain is more refractory to treatment than musculoskeletal pain, can occur at any time following injury, even years following their initial injury, with a low frequency of spontaneous recovery.

There are several proposed mechanisms for the origin of neuropathic pain after SCI. Pain may arise from a combination of generators: peripheral, spinal, and supraspinal (372). Peripheral sources may include impingement of nerve roots, resulting in radicular-at-level neuropathic pain. Spinal pain

may be from an “irritated focus” or “neural pain generator” located at the injury site, as there are cases of spinal blockade with anesthetics abolishing pain. In some cases spinal anesthetic blockade does not always relieve pain and thereby supraspinal pain may be from the presence of thalamic neurons with abnormal patterns of activity. GSWs, neurologically incomplete, and CE injuries may be predisposing factors that increase the risk of developing neuropathic pain. Psychosocial deficiencies may predict subjective pain complaints. Individuals who are depressed, anxious, or experience severe stress are more likely to have pain (373), while those who are active and working are less prone to complain of pain.

Unfortunately, although many treatments for neuropathic pain have been tried, few have been found to be effective in controlling SCI neuropathic pain. The focus should be symptomatic relief and helping the patient manage with the pain rather than complete elimination of the pain. Treatments used include medications, such as anticonvulsants, antidepressants, local anesthetics, and NMDA antagonists and invasive procedures such as intrathecal drug administration and surgery. Satisfactory relief, defined as a 50% reduction in pain, is at best found in one third of subjects in controlled trials.

Anticonvulsants, most notably gabapentin and pregabalin, are increasingly being used as first-line agents and have shown effectiveness in patients with SCI-related neuropathic pain (374,375). Carbamazepine and oxcarbamazepine have been used although controlled trials have not been performed (372). Tricyclic antidepressants (TCAs) have been commonly prescribed. A recent randomized trial found amitriptyline (maximum dose of 50 mg TID) to be more effective than gabapentin (maximum dosage of 1,200 mg TID) (376). TCAs combined with anticonvulsants may be more effective than either drug alone. TCAs are contraindicated in patients with ischemic heart disease, heart failure, cardiac conduction disturbances, and a history of seizures. Sedation and anticholinergic effects such as dry mouth and constipation are of concern in the population with SCI. SSRIs are effective antidepressants and have a better side effect profile, but have not shown improvements in pain. Randomized controlled studies involving trazodone, mexilitine, and valproate have not shown a consistent benefit. Opiates are effective, but not without controversy, especially in SCI where side effects such as constipation are notable (377).

The efficacy of intrathecal medications are confined to case series and should only be considered if conservative measures have failed. Morphine and clonidine have shown benefit and the combination of the two ITB can also be effective if pain is spasticity-related.

Surgical treatments including spine fusions or nerve decompression are useful for treating pain originating from spine instability or syringomyelia. Ablative surgeries such as corpectomy, corpectomy, and myelotomy are controversial. Several studies have not found any advantage to spinal cord stimulation (378,379). DREZ lesions are thought to be indicated for some cases of neuropathic pain at the level of injury, while those with below level neuropathic pain had poor results (380). ES of the brain has shown some positive impact on pain in SCI (381).

Nonpharmacological and nontraditional approaches to neuropathic pain in SCI are frequently used. These include massage, marijuana, acupuncture, chiropractics, biofeedback, magnets, and hypnosis. Among these, massage reportedly gave the most relief followed by marijuana in a sample of persons with SCI (363). Exercise may increase circulating beta-endorphin levels, a substance known to be associated with analgesia. Psychological counseling reportedly provided years of relief for 20% of the sample (363).

### UE NeuroMusculoskeletal Pain

The upper limbs in persons with SCI are used for weight-bearing activities including weight shifts, transfers, and wheelchair propulsion as well as for ADL, thereby increasing the chances of overuse syndromes. Shoulder pain is the most commonly reported painful joint after SCI (382). Approximately 30% to 50% of patients complain of shoulder pain severe enough to interfere with function, with the prevalence increasing with time from injury (366,383). Pain during the first year after injury is more common in tetraplegics, but in later years it is more common in paraplegics. Since the person with SCI relies extensively on their upper limbs, any further loss of upper limb function because of pain may have adverse effects on functional independence (384,385).

Two thirds of shoulder pain is due to chronic impingement syndrome and approximately half involves rotator cuff pathology. Bicipital tendonitis, subacromial bursitis, adhesive capsulitis, acromioclavicular osteoarthritis, and cervical radiculopathy are other common causes of shoulder pain in chronic SCI. Other causes that are specific to SCI include muscle imbalance, spasticity, contractures, HO, and the presence of a syrinx. If pain develops acutely, then referred pain should be excluded, including UTI, peptic ulcer disease, angina, and an acute abdominal problem. Pain associated with neurologic changes (i.e., weakness, sensory loss, and/or reflex changes) may be due to peripheral nerve entrapment, radiculopathy, or a post-traumatic syrinx.

Range of motion, strength and sensory testing, provocative tests for specific abnormalities (e.g., Tinel, Phalen, Adson), and a functional assessment should be performed including an evaluation of the patient's posture, function (i.e., pressure reliefs, wheelchair mobility, ADL, transfers), and home/work environment. Diagnostic tests should be ordered as needed. The Wheelchair User's Shoulder Pain Index (WUSPI) is a 15-item self-report instrument, with a range of 0 to 15 that measures shoulder pain intensity during various ADL utilizing a visual analog scale (385,386). This is often used to monitor the effectiveness of treatment.

Relief of acute pain includes rest, icing, and other modalities along with pharmacologic intervention (NSAIDs, acetaminophen, muscle relaxants) and injections, as needed. Acupuncture may also be helpful (387,388). Once overuse problems arise, they can become a chronic problem if treatment is not focused on correcting the cause. Complete rest of a painful shoulder is difficult but decreasing stress on the joints should be encouraged by utilizing compensatory techniques (e.g., using a transfer board rather than performing lateral

transfers, or performing lateral or anterior weight shifts rather than push-up weight shifts).

After the pain has subsided, emphasis should be focused toward preventing further injury by obtaining a balance in strength and flexibility of the musculature surrounding the shoulder (389,390). The most often described muscle imbalance is the tightening of anterior muscles without development of proper strength in posterior stabilizing muscles (366). A proper wheelchair and back support will also play a role in preventing shoulder pain. Surgery is not typically performed for patients with rotator cuff tears, as patients require prolonged immobilization postoperatively, creating a period of extreme disability and loss of independent function (366,391). However, there may be some benefit for pain and a small study reported improved strength and ROM with surgery, and therefore can be considered for those who fail conservative management, who are compliant, and in whom postoperative immobilization is not a limiting factor (392).

Overuse injuries may also affect the elbow (32%), wrist, and hand (45%), including the development of carpal tunnel syndrome (CTS), ulnar nerve entrapment at the elbow and wrist, de Quervain syndrome or other tenosynovitis, osteoarthritis, and stress fractures (384). The most common source of elbow pain is overuse of the extensor and flexor tendons as they attach to the medial epicondyle. Ulnar neuropathy can lead to intrinsic hand weakness and medial hand numbness, and can impact ADL (366). The incidence of CTS is between 21% and 65%, with persons with paraplegia more affected than persons with tetraplegia (380), and with a higher incidence at longer times postinjury (393). This is due to recurrent stress from transfers, wheelchair propulsion, and pressure reliefs. Treatment for CTS includes analgesics, NSAIDs, splinting (especially at night), injections (anesthetic and/or corticosteroid), physical modalities (ultrasound, friction massage, etc.), and education regarding transfers to avoid end-range stress. The use of padded gloves may decrease the trauma of wheelchair propulsion. Surgical release may be required, with the postoperative recovery time being weighed against the long-term benefits of the procedure.

Since much of the chronic upper limb musculoskeletal problems are due to the overuse from functional activities, it is vital that proper exercise techniques and shoulder protection, and conservation should be learned early during acute rehabilitation and reinforced frequently. Often one hears the phrase "no pain, no gain"; rather the SCI team should teach their patients to "conserve it, to preserve it" (394).

Spine pain is not uncommon. In patients with incomplete SCI, mechanical pain of the spine may be the result of muscle imbalances, however, the source in persons with complete SCI are less well understood. Considerations should include spasticity, vertebral osteomyelitis, and Charcot spondyloarthropathy (395). A comprehensive workup should be initiated.

### Post-Traumatic Syringomyelia

The most common cause of progressive myelopathy after a SCI is post-traumatic syringomyelia (PTS). PTS may develop at any

time, from 2 months to decades postinjury (337,396–399). PTS presents as neurologic decline in up to 8% of patients, but is more frequently first seen on MRI as an elongated cavity in a much higher percentage of cases. The pathogenesis is unknown, but the cavity begins at the level of the cord injury in the gray matter between the dorsal horns and posterior columns. Initiating factors include cord hematoma, residual spinal canal stenosis or compression, and spinal kyphotic deformity. The cyst may extend rostrally and/or caudally, compressing the cord, by dissecting through the intermediate gray matter, and may result from increases in subarachnoid fluid pressure due to intra-abdominal or intra-thoracic pressure increases (i.e., cough, sneeze, straining or valsava, weight-lifting, forward-lean pressure release, and quad coughing).

Early signs and symptoms of PTS are often nonspecific and variable; some patients with a markedly elongated syrinx may have minimal symptoms. The most common presenting symptom is pain, usually located at the site of the original injury or may radiate to the neck or upper limbs. The pain is described as aching or burning, often worse with coughing, sneezing, straining, and in the sitting rather than in the supine position. The earliest sign is an ascending loss of deep tendon reflexes. An ascending sensory level is common, typically with a dissociated sensory loss with impaired pain and temperature sensation but intact touch, position, and vibration sense. Loss of pain sensation can lead to a Charcot joint. Weakness occurs, but rarely in isolation. Additional findings may include increased or decreased spasticity, hyperhidrosis, AD, neck muscle fatigue with prolonged sitting, loss of reflex bladder emptying, worsening OH, scoliosis, central and/or obstructive sleep apnea, new Horner’s syndrome, reduced respiratory drive, diaphragmatic paralysis, cranial nerve dysfunction, impaired vagal cardiovascular reflexes, and sudden death (337,396,398,400).

MRI with gadolinium is the gold standard for diagnosing PTS. MRI characteristics that are often associated with neurologic decline include those that are longer and wider, those with poorly demarcated T2-weighted signal hyperintensity at the rostral extent, a flow void sign on T2-weighted images suggesting high pressure, and those associated with spinal stenosis (399). If an MRI cannot be performed, a CT myelogram with delayed imaging can be utilized. Electrodiagnostic findings are occasionally used to aid in the diagnosis (396,401,402).

A syrinx may spontaneously resolve, progress, and then plateau or progress continuously. Neurologic monitoring is essential, and includes clinical examination, serial electrodiagnostic tests, and/or MRI. Conservative treatment includes close monitoring, pain control, activity restrictions, and providing rehabilitation interventions as needed (i.e., functional training and adaptive equipment). Activity restrictions include avoiding maneuvers that increase intra-thoracic/abdominal pressure, that is, high-force exercise; valsava, Crede, and quad coughing with direct compression over the IVC; avoiding anterior weight reliefs and weight lifting, especially if these activities exacerbate symptoms. Surgical treatment is usually indicated if there is an ongoing neurologic decline or severe intractable pain. Surgical treatments include shunting (syringo-subarachnoid,

syringo-pleural, or syringo-peritoneal), reconstructing the subarachnoid space with dissection of arachnoiditis/meningeal scarring and duraplasty, and corpectomy (403–405). Surgery yields improved strength and improved pain control in some but not all, whereas sensory recovery is not usually as favorable. Reduction of syrinx size on postoperative MRI usually predicts a good surgical result; however, complete resolution of the syrinx is not necessary for a good clinical outcome. Recurrence of neurologic symptoms is common (up to 50%).

Surgical Interventions of the UE in Tetraplegia

Surgical interventions can improve the functional mobility in appropriately selected persons with tetraplegia. Tendon transfers, arthrodesis of the interphalangeal joints of the thumb, and implantation of an UE neuroprosthesis system are procedures that can be utilized alone, or more commonly, in combination, to improve motor function by one level (406). As a general rule, delay of surgery for 1 year allows adequate time for neurologic stabilization. Components of the preoperative evaluation include measurements of UE strength, sensation, ROM, and spasticity. Vocational and recreational activities should also be noted (407). Discussing the anticipated outcomes and the postoperative recovery plan prior to the procedure allows patients and clinicians to establish realistic expectations.

The International Classification of the upper limb in tetraplegia has been utilized to standardize communication regarding tendon transfer surgery (264) (Table 27-11). In

TABLE 27.11 Modified International Classification for Individuals with Tetraplegia	
Motor Group	Functional Muscles <sup>a</sup>
0	Weak or absent BR (grade 3 or less)
1	BR
2	BR, ECRL
3	BR, ECRL, ECRB
4	BR, ECRL, ECRB, PT
5	BR, ECRL, ECRB, PT, FCR

contrast to the ASIA classification, functional muscle strength is considered grade 4 or 5 rather than 3 or greater (408). This is because muscles used for transfer generally lose one strength grade and therefore, those with a grade of 3 or less prior to surgery may not have sufficient strength for functional tasks following the transfer. Spasticity in the proposed transferred muscle should be minimal or absent. Shoulder ROM and strength should also be quantified as both are needed for ultimate placement of the hand. ROM of the wrist and fingers should be full for all procedures involving the hand, and for the posterior deltoid or biceps to triceps transfer there should be functional ROM at the shoulder and no more than a 30-degree elbow flexion contracture. The sensory evaluation consists of the Weber two-point discrimination test at the pulp of the thumb (409). Cutaneous sensation is considered present if the patient can distinguish objects less than 10 mm apart and a grade of ocular-cutaneous (O-Cu) is given as this is predictive of sufficient proprioception to allow for hand function without visual cues, as this will allow for ease with ADL. Those who are unable to distinguish objects less than 10 mm are placed in the O-group. If cutaneous afferents are present, both extremities may undergo surgical reconstruction, but it is advisable to perform surgery on only one extremity at a time.

Behavioral evaluation of potential surgical candidates is extremely important. Because the recovery phase will involve a period of immobilization, activity restriction and rehabilitation, patients must be able to adhere to all phases of the recovery plan. During this process, patients will require more assistance from caregivers, modification of work/leisure activities, and adaptive strategies for ADL/mobility. Each surgery is limited to one extremity, with the stronger extremity being operated first. Facilitating hand opening and closing via tendon transfer may require two separate procedures.

The most common procedures for persons with a C5 level include the transfer of the BR to the extensor carpi radialis brevis (ECRB) to restore wrist extension (improvements in lifting objects, feeding, grooming, and hygiene is gained) and deltoid to triceps to provide elbow extension (410,411). This latter transfer enables patients to stabilize themselves for sitting and transferring, and to reach overhead against gravity, improving grooming, personal hygiene, pressure relief, writing speed and clarity, and self-feeding (412). The goal, however, should not be to improve the ability to perform transfers, since the latissimus dorsi, the prime shoulder depressor muscle, is lacking. A biceps to triceps transfer can also be performed (413,414).

At the C6 functional level, the Moberg “key grip” procedure may be performed to restore the lateral or “key” grip in patients without a natural tenodesis (415,416). Improvements in functional activities include grooming, eating, writing, and desktop skills and these are maintained over time (417). Transfer of an active muscle, like the BR or others, to the flexor pollicis longus (FPL) to provide lateral pinch and to the finger flexors to provide grasp, provides better function and is preferable to Moberg’s simple FPL tenodesis (418–420). Posterior deltoid to triceps transfer may also be performed in C6 patients. This procedure is recommended prior to hand reconstruction, or

simultaneously without diminishing outcomes. A supination contracture of the forearm that may occur in individuals with C5 and C6 motor injuries can be corrected by rerouting of the biceps brachii around the radial neck (421).

At the C7 level, the goal is to restore active grasp and improve hand control. Transfer of the BR to FPL can achieve restoration of thumb flexion. Restoration of finger flexion is achieved through transfer of ECRL or flexor carpi ulnaris to the flexor digitorum profundus (FDP). At the C8 level, an intrinsic minus or “claw hand” posture results. A lumbrical bar that prevents hyperextension of the metacarpal phalangeal may improve a patient’s function, and surgery is rarely indicated.

Postoperative immobilization of the extremity in a cast is usually between 1 and 3 months. The patient should be instructed in proper elevation techniques to control edema. Once the patient is cleared for ROM, a removable thermoplastic splint is fabricated to protect the tendon transfers from over stretching. Scar management may include breaking down adhesions and desensitization techniques. Biofeedback and therapeutic ES can help reeducate muscles following tendon transfers (422,423). Activities are graded progressively by performance time and resistance applied, eliminating any that create heavy resistance to the tendons until after 3 months. Data suggests that benefits from transfer procedures are maintained and patient satisfaction remains high (424,425).

The Freehand system is a neuroprosthesis that was previously implanted in patients with C5 or C6 tetraplegia. Movement of the contralateral shoulder facilitates control of the opposite hand to allow for grasp. The procedure can be performed in association with tendon transfers. Home use of the device and satisfaction with the neuroprosthesis is high (426–428), however, at the time of writing this chapter, this system is not available. Newer techniques of surgery with FES include advanced controls to allow individuals with C4 and higher lesions or C7 lesions to take better advantage of the neuroprosthesis, and nerve grafting for persons with C4–5 level of injury with LMN injuries. The nerve graft is attempted to restore volitional control or to reverse flaccid paralysis into spastic paralysis for application of FES (429).

## PSYCHOLOGICAL ISSUES

SCI is a life-altering event for patients and their families. It is, therefore, not surprising that patients have a myriad of adjustment issues postinjury.

A person who sustains a SCI is at risk for the “four D syndrome”; dependency, depression, drug addiction, and, if married, divorce (430). Psychological issues such as depression will have an impact on functional capabilities (431).

Depressive disorders are the most common form of psychological distress after SCI, estimated to affect 20% to 45% of those injured, and usually occurs within the first month (432–435). All members of the rehabilitation team should be aware of signs of evolving depression in this population and react appropriately. Risk factors for depression include a prior history or

family history of depression, pain, female gender, lack of social support, multiplicity of life stresses, concurrent medical illness, and alcohol or substance abuse. Additional factors include having a complete neurological injury, medical comorbidity with TBI, a low level of autonomy, poor education, unemployment, having a poor social network and family support, few financial resources, architectural barriers, vocational difficulties, and the need for personal and transportation assistance.

The suicide rate for individuals with SCI is approximately five times the age-sex specific suicide rate in the United States. It is the leading cause of death in individuals with SCI in the youngest age groups, and is highest 1 to 5 years postinjury (22,436,437). The suicide rate is higher for those “marginally” injured (incomplete injuries) who have a near complete recovery (438). In addition to depression, lack of social support, history of suicide attempt, and a feasible plan for inflicting harm to self are risk factors for suicide. Substance abuse, which is increased in the SCI population, is also a major risk factor for suicide. It is imperative that physicians and other health care personnel continue to monitor patients for depression well after the acute phase of injury.

Anxiety and post-traumatic stress disorder (PTSD) have been reported in up to 20% of persons with SCI (439). Symptoms of PTSD may be higher in those with features of depression and/or anxiety (440).

The treatment for psychological disturbances after SCI includes counseling and pharmacological intervention. Medications should be considered for individuals who present biological, somatic, and/or mood-related symptoms of sufficient severity to disrupt the person’s life and ADL. The medications should continue for at least 4 months (441,442), and be tapered slowly as discontinuation early is associated with a high rate of relapse (443). After this initial period, medication may need to be continued to prevent recurrence of symptoms. A psychiatrist should be consulted if the patient has suicidal ideation or presents with psychotic features, and/or the patient does not respond to one or two of the trials of antidepressant medications. Recurrence rates for depression are common.

There is a direct relationship between QOL scores and length of injury, suggesting that people may adapt to their injury with time. Individuals injured at a younger age tend to experience successful adjustment and a better QOL than older individuals (444). This may be due to their flexible use of coping strategies, and the development of a self-concept that includes the knowledge of future limitations (445). Additional variables associated with lower QOL scores included presence of neurogenic pain, spasticity, and bowel and bladder problems (446). Conversely, those who are married, currently employed, more highly educated, female, and Caucasian are more likely to have higher QOL scores (447,448). Interestingly, the QOL for persons with a high level of injury have been underestimated by health care professionals (449).

### Substance Abuse

Substance abuse is frequently encountered in SCI. The CAGE, a four-question screening device for alcoholism, is a reliable

instrument with the SCI population (450). At-risk drinkers and substance users tend to be younger, single, male, and less educated. Those with higher CAGE scores have a higher incidence of medical complications, including more pain, PUs, and lower satisfaction with life (451,452).

Alcohol and drug misuse contributes to SCI by increasing risk taking while intoxicated, hampers learning and rehabilitation gains, interferes with self-care, places persons at risk for complications, contributes to depression, mortality and morbidity, and limits long-term outcomes, and capacity for independent living (451–454). Heavy drinkers prior to injury spend less time in educational and vocational activities while in a rehabilitation hospital, and alcohol users are less motivated to participate in their rehabilitation than nondrinkers (455). Substance abuse prevention and treatment programs should be included as part of the SCI rehabilitation.

## SEXUALITY AND FERTILITY

Sexuality issues should be discussed with the individual soon after the injury as part of the SCI education during inpatient rehabilitation. Aspects for discussion for men include the options for erectile function and capability to father children. Greater than 90% of men with complete and incomplete UMN lesions can achieve reflexogenic erections (456). Patients with complete UMN injuries have a less than 10% chance of achieving psychogenic erections, but approximately 50% of those with an incomplete UMN lesion may. While the majority of men with UMN lesions are able to obtain reflex erections, these erections are often poorly sustained and often are inadequate for intercourse. For persons with a complete LMN lesion, up to 12% can achieve reflexogenic erections, with approximately 25% being able to achieve psychogenic erections (456).

There are several treatment options available for erectile dysfunction. The phosphodiesterase class of medications, including sildenafil and vardenafil, has been used with success in the SCI population with UMN lesions (457–459). Hypotension is a potential adverse side effect with these medications and should not be used in patients taking nitrates (460). Patients at risk for AD should be so cautioned. Intracorporeal injections with prostaglandin E1 can induce an erection in those with UMN and LMN injuries. This should not be used in persons with sickle cell disease and the patient should be aware of the risk of priapism. Additional methods include penile implants, and vacuum and ring devices. Penile implants are effective, but have a relatively high failure rate and may cause infections or penile erosion.

Male fertility is variably affected by SCI. Retrograde ejaculation is reported to occur in 37% to 100% of men with SCI (461). Approximately 5% of men with complete UMN lesions and 18% of those with LMN lesions have ejaculations. The percentage is higher in those with incomplete injuries. Achieving ejaculation, however, does not insure successful reproduction. Less than 10% of couples will have successful spontaneous

pregnancies (462). Therefore, patients who experience infertility should be evaluated by a reproductive specialist soon after the decision to attempt pregnancy is made. Semen analysis in men with SCI reveals decreased sperm count and decreased sperm motility. To obtain sperm in men who do not ejaculate, penile vibratory stimulation (PVS) and if unsuccessful, electroejaculation (EEJ) can be attempted. As a last resort, direct testicular extraction of sperm can be performed. Couples have had success with *in-vitro* fertilization (IVF), gamete intrafallopian transfer (GIFT), intracytoplasmic sperm injection (ICSI), and intrauterine insemination procedures (463).

For women, SCI does not affect female fertility once menses returns. Immediately following SCI, amenorrhea occurs in 85% of woman with cervical and high thoracic injuries and 50% to 60% of woman overall. Within 6 months and 1 year postinjury, 50% and 90% of women have return of menstruation. The completeness of injury does not appear to influence the menstrual cycle. With menstruation, women with SCI report increased spasticity, bladder spasm, and dysautonomia. Women with SCI experience menopause at similar ages to women without SCI.

Libido is generally preserved after injury and physiologic parameters of sexual function in women with SCI have been described (465). Preservation of psychogenic genital vasocongestion is associated with the preservation of sensation in the T11-L2 dermatomes (464). Reflexogenic vasocongestion can be induced via manual genital stimulation in women with UMN injuries. Approximately 50% of all women with SCI are able to achieve orgasm, although time to orgasm is prolonged compared to women without SCI (466). Women with LMN injuries affecting the S2-5 levels have reduced ability to achieve orgasm. Sildenafil has been shown to improve subjective arousal when used with manual stimulation, and may improve genital vasocongestion as well (466).

Pregnancy presents a unique set of potential problems for women with SCI. Women may develop PUs, recurrent UTIs, increased spasticity, or decreased pulmonary function during pregnancy. There is a slightly increased incidence of preterm labor in SCI women (467). AD may develop in susceptible women during labor. Pre-eclampsia can be difficult to distinguish from AD, however, once the diagnosis of AD has been made, epidural anesthesia is the treatment of choice. The epidural should continue at least 12 hours after delivery or until the dysreflexia resolves. Patient should be followed closely by the SCI physician in cooperation with the obstetrician (see Chapter 51 for more details on the above).

### **Cardiovascular Disease, Obesity, and Diabetes After SCI**

Cardiovascular disease (CVD) is a leading cause of mortality and morbidity in chronic SCI. In contrast to the able-bodied population, CVD occurs more frequently and at earlier ages in the SCI population (468,469). Several factors contribute to this increased incidence, including relatively sedentary lifestyle, poor dietary habits, dyslipidemia, increased prevalence of obesity and diabetes mellitus. Those with tetraplegia and

neurologically complete injuries are at highest risk (470). The prevalence of CVD has been reported between 25% and 50% (468,469,471).

The pathophysiology of CVD in persons with SCI is multi-factorial. Changes in body composition occur and include decreased fat-free body mass and a relative increase in adipose tissue. The relative decrease of fat-free body mass contributes to lowered high density lipoprotein (HDL) levels, impaired glucose metabolism, and progressive insulin resistance (472,473). Given the prevalence of CVD in the SCI population, early recognition of risk factors is crucial to initiate early interventions which can modify these risks. The American Heart Association (AHA) identifies age (men >45 years, women >55 years, or post-menopausal), hypertension (SBP  $\geq$  140 or DBP  $\geq$  90), diabetes, smoking, HDL less than 35 mg/dL, family history of CVD in first degree relative, and obesity as significant risk factors (474). These guidelines have been established for the able-bodied population and may not be as reliable in predicting CVD risk in the SCI population. For example, body composition characteristics unique to those with SCI make traditional BMI measures less accurate in predicting body fat (475–478). Individuals with SCI also often have lowered BPs; therefore, the definition of hypertension established by the AHA may need to be modified for this population. Hypertension in the SCI population has been defined as increase of at least 20 points above the individual's baseline.

Interventions to decrease the risk of cardiovascular events should initially focus on modifiable risk factor reduction including smoking cessation, weight loss, dietary modification, and increased physical activity levels. Those with hypertension, dyslipidemia, or hyperglycemia that persists after attempted behavior modification should receive appropriate pharmacotherapy (479). A structured exercise regimen is recommended (480). Arm ergometry (high intensity with a target HR of 70% to 80% of max predicted) and FES have shown efficacy in improving glucose tolerance and lipid profiles in persons with SCI (481–483).

Acute exercise responses and capacity for exercise conditioning are related to the level and completeness of the spinal lesion. Patients with complete SCI at or above T4 have diminished cardiac acceleration with maximal heart rates less than 130 beats/min (484). The work capacity of these persons is limited by reductions in cardiac output and circulation to the exercising musculature. Persons with paraplegia also have reduced exercise capacity and increased heart rate responses (compared with the nondisabled), which have been associated with circulatory limitations within the paralysed tissues.

The true incidence of obesity within SCI is likely underreported given the measures used to typically measure adiposity. Estimates (using % body fat) conclude that two thirds of persons with SCI are obese (485). Unfortunately, the presence of paralysis makes effective weight loss more difficult for wheelchair users. Recommendations for CV exercise include exercise at least three times per week (more to facilitate weight loss) for up to 90 minutes/d incorporating cardiovascular conditioning and strength training. Caution should be taken to avoid overuse

injuries to the UEs commonly seen in this population (486). Obesity has been associated with breast and colon cancer, CTS, stroke, coronary artery disease, diabetes mellitus, hypertension, dyslipidemia, obstructive sleep apnea, and PUs (485,487).

Diabetes mellitus has been reported to occur in approximately 20% of individuals with chronic SCI. Studies have shown that oral glucose tolerance testing may detect insulin resistance earlier than fasting blood glucose measures (488,489). Early detection is helpful in initiating early treatment, a key component to minimize the long-term complications associated with diabetes mellitus including chronic skin ulcers, peripheral vascular disease, heart attacks, and strokes. Symptoms of hyperglycemia include polydipsia and polyuria. In the SCI patient population, polyuria may include increased ICs volumes, new onset urinary incontinence, or AD. The measurement of the hemoglobin A1C is also helpful in making the diagnosis of diabetes mellitus and monitoring the efficacy of treatment.

### Long-Term Follow-Up

Long-term follow-up with a SCI specialist is extremely important, especially with shorter LOS in acute rehabilitation after injury. Initially, visits should occur on a monthly basis, especially while the person is on outpatient therapy. This allows for monitoring of medical issues, reevaluation of the therapy program, and updating goals and equipment prescriptions. As patients go home from inpatient hospitalization earlier, medical issues that previously were experienced in the hospital now may develop while at home. This includes bowel, bladder, and spasticity changes, and the possible development of HO, hypercalcemia, and AD. After medical issues have stabilized and outpatient therapy has concluded, visits are recommended every 3 to 6 months throughout the first year.

For those who are medically stable, at least yearly visits are recommended. Persons with SCI require regular and comprehensive health care throughout their lifetime. This includes routine health monitoring and care for nonSCI medical issues as well as for SCI-specific problems. The altered physiology and the absence of many typical symptoms for common problems following SCI pose a unique challenge for health care providers. The importance of these visits is also to review any medical changes, monitor the neurological examination for any changes, ensure the maintenance of the equipment, and prescribe any additional equipment that may be needed. Deterioration of the neurologic status may be secondary to a tethered cord, syringomyelia, or peripheral problems, such as median or ulnar nerve entrapment, or other musculoskeletal complications. As a greater proportion of persons with SCI are surviving after their injury, the importance of their follow-up visits to maintain their QOL cannot be overemphasized.

Guidelines for routine screening and preventive health care should be used as a starting point for people with SCI (490). Yearly evaluations should include the patient's current condition and concerns, medications, review of systems (ROS), and age-appropriate screening (491). Specifics include dental, vision, and hearing screens, evaluating for cognitive slowing,

depression, and suicide. Questions related to smoking, alcohol and drug use, exercise, and current employment status also should be included. Areas of focus should also include the unique issues of SCI and aging with a disability. An expanded ROS should address the specific problems common in SCI, including bladder and bowel control, appetite, sleep, BP, skin integrity, pain, spasticity, sexual function, equipment needs, and changes in strength, sensation, and functional ability.

In addition to a general physical examination, areas to examine include the skin, oral cavity in smokers, digital rectal examination for men over age 50, the SCI-specific neurological examination, and a musculoskeletal examination to identify problems related to aging with SCI and pain. A gynecologic evaluation is recommended for a clinical breast exam for women over 50 and a pelvic examination.

Counseling is an important aspect of follow-up visits, both for medical as well as physical and social issues. Lifestyle issues to review include diet and nutrition, smoking, physical activity, wheelchair and other equipment maintenance and safety, PU prevention, compliance with the individual's bladder management program, and advice against alcohol abuse.

Recommendations for the general medical screening should be followed in persons with SCI, including screening for colon cancer with a flexible sigmoidoscopy for those over age 50, and colonoscopy if at high risk. Mammography is recommended for women every 1 to 2 years between the ages of 50 and 69. Fasting glucose every 3 years for those over age 40 or annually for persons with risk factors for type-II diabetes, screening for nutritional deficiencies with complete blood count, albumin and iron levels (if at risk), fasting lipid profile for men over 40 and for women over 50, and prostate-specific antigen testing in men between age 50 and 70 or after age 45 if at increased risk, are also recommended (491). There have been few studies formally evaluating these recommendations in the SCI population (see Chapter 57 for more details of primary care management for persons with disability).

At times, readmission to the rehabilitation hospital for medical (e.g., PU, AD) or rehabilitation issues may be needed. For medical issues, the SCI physician and team are able to care for the patient with consultation of other specialists, as required. This includes the importance of maintaining the proper bowel and bladder programs, skin issues, and awareness and knowledge of treatment for AD. In addition, many times the person with SCI may require a "refresher course" in rehabilitation techniques that can best be taught in an intensive inpatient setting.

Secondary medical complications are extremely common in patients with chronic SCI. The most common reasons for rehospitalization include GU complications, PUs, and respiratory complications (173,317). Pneumonia is more common in persons with tetraplegia while pressure sores are more common in persons with paraplegia. Rehospitalization rates have remained static over the last 10 years (317). Patients from skilled nursing facilities, with lower motor FIM scores, or using state or federal health insurance plans, have higher rehospitalization rates.

## THE FUTURE

The quest for cure is as strong as ever, with many new advances constantly being made. Over the last decade, there is increased knowledge regarding the basic pathophysiology of SCI and new pharmacological strategies in the acute and chronic treatment to enhance neurological and functional recovery. In animal models, scientists have successfully used antibodies to block growth inhibitors, applied growth factors, implanted cells and peripheral nerve bridges, and used gene therapies to stimulate spinal cord regeneration. Some advances are nearly ready for application in the clinical setting. The key factors for cure include minimizing secondary effects of injury, neutralizing the effects of substrates that inhibit CNS regeneration, delivery of regeneration-promoting substances to the injured spinal cord, allowing a bridge to which the spinal cord axons can attach and grow along after injury, and determining the genes that may allow for “turning on” axonal growth after injury (see Chapters 81 and 82 for more details).

Basic science research continues to make progress with the ultimate goal of a cure for SCI. Rehabilitation is a crucial part of any cure treatment strategy and is what we currently have available to maximize functional potential. Rehabilitation professionals should be involved in the research but remain committed to the patients and their needs. Caring for the acute and long-term medical issues, as well as assisting the patient to be active in all domains including social, recreational, and vocational activities, is what rehabilitation is all about!

# Adult Motor Neuron Disease\*

## INTRODUCTION

Adult motor neuron disease (MND) is often considered synonymous with amyotrophic lateral sclerosis (ALS). In the United States, the term ALS is frequently used to describe all forms of adult-onset MND. However, it is also used to refer specifically to the most common form of adult MND, which is sporadic, acquired ALS. In the United Kingdom, the converse is true where the generic term for all forms of ALS is MND (1). In reality, adult MND actually encompasses a group of disorders that include ALS; primary lateral sclerosis (PLS); progressive muscular atrophy (PMA); progressive bulbar palsy (PBP); adult-onset, progressive spinal muscular atrophy (SMA); and X-linked, recessive spinobulbar muscular atrophy (SBMA). A presentation with pure upper motor neuron (UMN) signs may be called PLS, whereas pure bulbar presentation may be called PBP, and pure lower motor neuron (LMN) presentation called PMA. Whether these conditions exist as distinct diseases or rather represent part of the spectrum of ALS is still debated. This is represented schematically in Figure 28-1.

At least one form of PLS with a benign course and autosomal dominant inheritance has been reported (2,3). ALS is also referred to as Lou Gehrig's disease, named after perhaps the most famous person yet afflicted with the disease. SBMA

is commonly referred to as Kennedy's disease, named after the physician who first described this disorder in 1968 (4).

For the purposes of this chapter, we will use the terms ALS, PLS, PMA, PLS, SMA, and SBMA. In the adult population, ALS is far more common than the other disorders. Thus, ALS will constitute most of the focus of this chapter, which starts first with a description of the diseases, including epidemiology and genetics. This is followed by diagnostic workup, including electrodiagnosis, pharmacological management, and rehabilitation strategies, most of which may be applied to any of the adult MNDs.

## OVERVIEW OF THE MAJOR ADULT MNDs

### Amyotrophic Lateral Sclerosis

ALS is a rapidly progressive neuromuscular disease that destroys both UMNs and LMNs, resulting in spasticity and diffuse muscular atrophy and weakness. The vast majority of ALS cases are presumably acquired and occur sporadically. However, approximately 10% of all ALS cases are familial amyotrophic lateral sclerosis (FALS) and usually inherited as an autosomal dominant trait. About 15% of these cases result from a gene defect on chromosome 21q12.1, which leads to a toxic gain of function in the antioxidant enzyme Cu/Zn superoxide dismutase (SOD1) (5,6). Over 100 unique SOD1 mutations have been identified (5–7). Emerging evidence suggests that these mutations result in increased oxidative stress for the motor neurons, leading to cell death, which is felt to be related to free radical toxicity (6,7).

The etiology of sporadic amyotrophic lateral sclerosis (SALS) and the other 85% of FALS is unknown. Increasing data suggest that excessive glutamate activity in the brain and spinal cord may play an important role. Glutamate is one of the main central nervous system (CNS) excitatory neurotransmitters in the brain, and excess levels of this chemical have been demonstrated in the serum, spinal fluid, and brain tissue of ALS patients (8,9). There appears to be reduced clearance of glutamate from critical motor control areas in ALS as well as decreased levels of glutamate transport protein (10,11).

### Epidemiology of ALS

ALS most commonly strikes people between 40 and 60 years of age with a mean age of onset of 58 years (12–14). The overall

**FIGURE 28-1.** Schematic representation of adult MNDs.

\*This chapter is lovingly dedicated in remembrance of my dear friend, co-author, colleague, and source of much inspiration, Dr. Lisa Stroud Krivickas.

prevalence rate in the worldwide population is somewhere between 5 and 7 per 100,000, making it one of the most common neuromuscular diseases worldwide (15). Further, population studies suggest that the incidence of ALS is increasing, although this is probably due, in large part, to people living longer and better recognition of the diagnosis (16,17). There appears to be a higher incidence in urban areas, felt to be related to environmental factors (17–19). The association of nutrient intake with the risk of ALS was investigated in a population-based case-control study conducted in three counties of western Washington State from 1990 to 1994 (20,21). The authors found that alcohol consumption was not associated with increased risk of ALS. Ever having smoked cigarettes was associated with a twofold increase in risk and a greater than threefold increased risk was observed for current smokers. Further, dietary fat intake was associated with an increased risk of ALS, while dietary fiber intake was associated with a decreased risk. Interestingly, consumption of antioxidant vitamins from diet or supplement sources did not alter the risk but glutamate intake was associated with an increased risk of ALS. The finding that cigarette smoking and glutamate consumption are risk factors for ALS is consistent with current etiologic theories that implicate glutamate excitotoxicity and oxidative stress in the pathogenesis of ALS. The associations with fat and fiber intake warrant further study and biologic explanation.

Considerable clustering has been demonstrated in the Western Pacific region of the world (15–17). Other sporadic cluster cases have been reported but without obvious environmental or causal factors (15). Men appear to be more commonly affected than women with a male-to-female ratio of about 1.5:1.0 (12).

Poor prognostic factors include older age at time of onset, bulbar and/or pulmonary dysfunction early in the clinical course of the disease, short time period from symptom onset to diagnosis, and predominance of LMN findings at the time of diagnosis (12,14–16).

More women than men present with bulbar symptoms, and the progression of bulbar palsy appears to be more rapid in women (20,21). Young males with ALS may have a longer life expectancy but overall the median 50% survival rate is 2.5 years postdiagnosis, except in patients with primary bulbar symptoms, where the 50% survival rate is only 1 year (22). Survival rates will obviously vary to a degree depending on the patient's decision to use or not use mechanical ventilation and a feeding tube (23). Nonetheless, by 5 years postdiagnosis the overall survival rate is only 28% (12,14,15).

Atypical, “ALS-like,” MNDs have been reported infrequently as a remote complication of several malignancies, including lymphoma and small cell carcinoma of the lung (24,25). These likely represent paraneoplastic syndromes and not a true manifestation of ALS (26). Regardless, patients with atypical MND should be screened for malignancy.

### Spinal and Spinobulbar Muscular Atrophy

There are many forms of SMA, all of which involve selective destruction of anterior horn cells. The various forms of SMA

are clinically dissimilar, with some rare forms affecting distal or bulbar muscles only. The most common forms are often referred to as types I, II, and III (27). These are mostly disorders of childhood and are usually inherited as autosomal recessive traits. SMA I, also known as Werdnig-Hoffman disease (WHD) or acute, infantile-onset SMA, is a severe disorder resulting in death before age 2 years. SMA II, also referred to as early-onset, intermediate SMA or chronic WHD, is less severe, with signs and symptoms becoming apparent in the first 6 to 18 months of life. SMA III, also known as Kugelberg-Welander disease (KWD), is a chronic, later onset disorder, associated with significantly less morbidity. Signs and symptoms of SMA III usually become apparent between ages 5 and 15 years. In prior studies looking at SMA II and III over a 10 year period, SMA II subjects showed marked weakness and progressive decline of strength while SMA III subjects had a relatively static or very slowly progressive course and were far stronger. In both SMA II and SMA III, proximal weakness was greater than distal. Joint contractures, progressive scoliosis, and restrictive lung disease (RLD) were present in most of the SMA II individuals but these complications were rare in SMA III (27). Scoliosis in a patient with SMA II is shown in Figure 28-2.

There are two forms of SMA that have onset in the adult age group. One is an adult-onset form of SMA with age of onset of 17 to 55 years with either recessive or dominant forms of inheritance (28,29). The disease clinically appears much like SMA III, although it may be more progressive. The other form

**FIGURE 28-2.** Scoliosis in a young boy with SMA type II.

is SBMA, or Kennedy's disease, a sex-linked, recessive MND characterized by progressive spinal and bulbar muscular atrophy, gynecomastia, and reduced fertility (4,30).

Adult-onset SMA, SBMA, and SMA III patients can have normal life spans, and many of the rehabilitative modalities discussed in this chapter are applicable to this population. Further, with the rapid advancement of rehabilitation technology, many SMA II patients are now living well into adulthood and successful pregnancies have been reported in this disease (31).

### Genetics of SMA

A detailed analysis of the 5q13 region revealed that this chromosomal region in humans contained a large inverted duplication with at least two genes present in telomeric and centromeric copies. Further studies have identified the SMA causative gene as the survival motor neuron 1 gene (SMN1, telomeric copy), along with a disease modifying gene (SMN2, centromeric copy) (32–35). Briefly, the two SMN genes are nearly identical except for a difference of only five nucleotides in their 3' regions, without any alteration of the amino acid sequence of the protein. However, the critical difference between SMN1 and SMN2 genes is a C-T transition located within the exon splicing region of the SMN2 that affects the splicing of exon 7. This change results in frequent exon 7 skipping during the splicing of SMN2 transcripts (32,33). It is thought that the resulting truncated SMN protein without its exon 7 contribution is a less stable form of SMN protein and is therefore rapidly degraded. In about 95% of SMA patients, both copies of SMN1 exon 7 are absent due to mutations. In the remaining SMA affected patients, other small or subtle mutations have been identified (33,34).

Genetic studies have now established that SMA is caused by mutations in the telomeric SMN1 gene, with all patients having at least one copy of the centromeric SMN2 gene. At least one copy of the SMN2 must be present in the setting of homozygous SMN1 mutations; otherwise, embryonic lethality occurs. The copy number of SMN2 varies in the population, and this variation appears to have some important modifying effects on SMA disease severity (34). It appears that higher number of SMN2 copies in the setting of SMN1 mutations results in less severe clinical SMA phenotype. However, substantial variations in SMA phenotype and disease severity can exist with a given SMN2 copy number, so it is not recommended to predict disease severity based on SMN2 copy numbers. Although we now know that SMN protein is expressed widely in many tissues throughout the body, its function is still not completely understood at this time (35).

### Genetics of SBMA (Kennedy's Disease)

SBMA is a hereditary adult-onset disease that causes preferential degeneration of LMNs leading to weakness and atrophy of bulbar, facial, and limb muscles. It is clinically similar to ALS. The main clinical distinction between the two is that ALS involves degeneration of both UMNs and LMNs, whereas the affected cell types in SBMA are LMNs.

Another interesting difference to note is that Onuf's nucleus, an androgen-sensitive spinal cord motor neuron nucleus, is spared in ALS, although it degenerates in SBMA (30,35). Degeneration of sensory neurons of the dorsal root ganglia is also a typical sign associated with SBMA, often preceding the onset of motor dysfunction. In addition to the neurological phenotype, SBMA patients display some of the characteristic signs of androgen insensitivity syndromes including testicular atrophy, decreased fertility, gynecomastia, and elevated androgen levels (36). SBMA is caused by a novel mutation, the expansion of a trinucleotide CAG repeat, in the first exon of the androgen receptor gene (32). Unaffected individuals have a CAG repeat size that ranges between 5 and 35 glutamines, while symptomatic individuals always have a repeat size of at least 37 glutamines (32).

SBMA has some clinical variability; however, phenotypic expression does not correlate with the length of CAG repeats. This is in contrast to myotonic muscular dystrophy and fragile X syndrome, where increased numbers of tandem triplet repeats correlate directly with disease severity (30). Commercially available blood tests (DNA analysis) are now available for SMA and SBMA. SBMA can occur without any family history or gynecomastia and all males with atypical ALS should be tested for SBMA. Prevalence rates for SMA types II and III are estimated to range from as high as 40 per million among children to around 12 per million in the general population, with adult-onset SMA and SBMA being far less common (27).

## DIAGNOSTIC EVALUATION OF MND

The diagnosis of ALS and other forms of adult MND is primarily a process of exclusion. If, based on the history and physical examination, clinical signs and symptoms of MND are detected, one must generate a differential diagnosis and then work to exclude processes mimicking MND. Only in FALS with known SOD1 mutations, Kennedy's disease, and the few adult-onset SMA cases in which SMN mutations are detected is a definitive diagnostic test available. For most patients with ALS or its variants (PMA and PLS), electrodiagnostic testing (EDX), laboratory testing, neuroimaging studies, and, occasionally, a muscle biopsy are used to exclude other diagnoses. The El Escorial criteria (Fig. 28-3) are used to assess the certainty of a diagnosis of ALS once other disease processes have been excluded.

### Clinical Presentation

Patients with ALS most often seek evaluation complaining of focal weakness (60%), rarely of generalized weakness or cramps, and very rarely of generalized fasciculations or respiratory failure. Symptom onset may be anywhere within the motor system, including areas of the brain and brainstem as shown in Figure 28-4. Although fasciculations are a prominent feature in most patients with ALS, patients who complain of fasciculations only and have an otherwise normal neurologic

**FIGURE 28-3.** World Federation of Neurology El Escorial revisited criteria for ALS diagnosis.

examination usually have benign fasciculation syndrome and are unlikely to develop ALS. Symptom onset may be anywhere within the motor system.

The evaluation of a patient suspected of having MND begins with a detailed history, general physical examination, and neurologic examination. On neurologic examination, one is looking for evidence of UMN and LMN dysfunction. The mental status, nonmotor cranial nerve function, sensory examination, and cerebellar examinations should be normal. The symptoms may be quite insidious and develop slowly or in unusual motor patterns. Loss of function may not be initially obviously disabling but performance may be affected. This is demonstrated by the noted decline in Lou Gehrig's batting average over the last 10 years of his professional baseball career (Fig. 28-5).

Patients with UMN pathology often complain of loss of dexterity or a feeling of stiffness in the limbs. They may note weakness which is caused by spasticity resulting from disinhibition of brainstem control of the vestibulospinal and reticulospinal tracts. Findings on examination include spasticity and hyperreflexia, indicated by abnormal spread of reflexes and clonus or by the presence of brisk reflexes despite muscle atrophy due to LMN loss. The gold standard used to diagnose UMN pathology is the presence of pathologic reflexes, such as the Babinski's sign, Hoffman's sign, and jaw jerk. If the toe extensors are paralyzed, visualization of contraction of the tensor fascia lata when an attempt is made to elicit a Babinski response has the same significance as great toe extension. Recently, it has been suggested that the corneomandibular reflex may be a more sensitive and specific indicator than the jaw jerk of UMN pathology in the bulbar region (37).

**FIGURE 28-4.** Areas of the brain and brainstem involved in ALS.

Patients with LMN pathology usually present complaining of muscle weakness. In addition, they may note muscle atrophy, fasciculations, and muscle cramping. Cramping may occur anywhere in the body, including the thighs, arms, and abdomen. Cramping of abdominal or other trunk muscles raises a red flag urging the clinician to consider a diagnosis of ALS. Findings on examination include weakness, atrophy, hypotonia, hyporeflexia, and fasciculations. Head drop is a manifestation of muscle weakness often seen in ALS although it can be seen in other neuromuscular disorders; ALS and myasthenia gravis are the two most common causes of head drop. Atrophy often appears first in the hand intrinsic muscles. Although fasciculations are not a necessary criteria for the diagnosis of ALS, one should question the diagnosis when none are observed. A recent study identified the following hierarchy of initial symptoms: leg weakness in nearly half of ALS patients; followed by arms, bulbar muscles, and then generalized weakness (38). Presentation with only respiratory muscle weakness is extremely rare.

**FIGURE 28-5.** Batting average of Lou Gehrig during the last 10 years of his baseball career.

Signs and symptoms suggesting bulbar muscle weakness include dysarthria, dysphagia, drooling, and aspiration. These signs and symptoms may be caused by UMN and/or LMN dysfunction involving the bulbar muscles. Signs of spastic dysarthria, indicating UMN pathology, include a strained and strangled quality of speech, reduced rate, low pitch, imprecise consonant pronunciation, vowel distortion, and breaks in pitch. LMN dysfunction creates a flaccid dysarthria in which speech has a nasal and/or wet quality; pitch and intensity are monotone, phrases abnormally short, and inspiration audible. Complaints of difficulty chewing and swallowing, nasal regurgitation, or coughing when drinking liquids, may all indicate dysphagia. On physical examination, the following tests may be used to assess facial and bulbar muscle function: ability to bury the eyelashes, pocket air in the cheeks, whistle; jaw opening and lip closure strength, phonation of a variety of syllables such as “puh,” “kuh,” “tuh,” and “ah.” The tongue should be examined for fasciculations and atrophy and tongue strength and range of motion assessed. The gag reflex and jaw jerk should be assessed to look for UMN dysfunction. Pseudobulbar affect is a symptom of pseudobulbar palsy which refers to an UMN syndrome caused by motor neuron loss in the corticobulbar tracts. Patients experience inappropriate laughter or crying which is not concordant with their mood and can be embarrassing. Disinhibition of limbic motor control produces pseudobulbar affect, also sometimes called “emotional incontinence.”

In patients who present with respiratory failure, the earliest signs are often nocturnal and include poor sleep with frequent awakening, early morning headaches, excessive daytime fatigue and sleepiness, nightmares, and orthopnea. Frequent sighing, a weak cough, and difficulty clearing bronchial or pulmonary secretions are other signs of respiratory muscle weakness. Later signs of respiratory dysfunction are dyspnea with exertion, truncated speech, respiratory paradox, dyspnea when eating, rapid shallow breathing, visible accessory muscle contraction, and flaring of the nasal alae. With advanced, untreated respiratory failure, patients may have an elevated hematocrit, low serum chloride, respiratory acidosis with a compensatory metabolic alkalosis, hypertension, and cor pulmonale.

Other signs and symptoms frequently associated with ALS are cachexia, fatigue, and musculoskeletal complaints. The term “ALS cachexia” refers to a phenomenon experienced by some patients in which weight loss occurs in excess of that caused by muscle atrophy and reduced caloric intake. Both subcutaneous fat and peritoneal fat are lost, presumably because of acceleration of the basal metabolic rate (39). In patients with ALS cachexia, greater than 20% of body weight is typically lost over a 6-month period. Many patients with ALS feel an overwhelming sense of muscle fatigue which is probably due to a combination of blocking of neuromuscular transmission in reinnervated nerve terminal sprouts and impairment of excitation contraction coupling (39). Some patients seek initial medical attention because of fractures or sprains that do not heal. In reality, these patients probably sustained their initial injury because of a fall or other injury (e.g., sprained ankle) that occurred because of underlying muscle weakness; they were then unable to recover to their premorbid level of function because of that weakness. Other common musculoskeletal complaints include neck and back pain, shoulder pain due to a frozen shoulder, elbow flexion and ankle plantar flexion contractures, and claw hand. Patients may experience osteoporotic fractures and/or stress fractures because of immobilization-induced bone density loss.

Rare signs and symptoms which usually occur only in advanced ALS include sensory impairment, autonomic dysfunction, bowel and bladder dysfunction, extraocular muscle paralysis, pressure ulcer formation, and severe dementia. Although ALS is discussed as a pure motor disorder, some patients complain of paresthesias. These may be due to compression or entrapment neuropathies, but subclinical abnormalities in somatosensory evoked potentials and quantitative sensory testing have been reported (40).

### Differential Diagnosis

After obtaining a history and examining the patient, the clinician is able to generate a differential diagnosis which guides further diagnostic testing. The differential diagnosis differs depending on whether the presentation is primarily LMN, UMN, bulbar or mixed LMN and UMN.

### El Escorial Criteria

The El Escorial criteria (see Fig. 28-3) for diagnosing ALS were developed by a task force of the World Federation of Neurology in 1990 to ensure inclusion of more homogeneous patient populations in ALS clinical trials (41). These criteria have been used to enroll patients in most of the recent clinical trials. The criteria were revised in 1998 to improve the speed and certainty of diagnosis (42). The criteria classify the certainty level of the diagnosis of ALS as falling into one of five categories: definite, probable, probable with laboratory support, possible, and suspected. In brief, the motor system is divided into four regions: bulbar, cervical, thoracic, and lumbosacral. Clinical evidence of UMN and LMN pathology is sought in each region. The certainty level of diagnosis depends on how many regions reveal UMN and/or LMN pathology. Figure 28-3 summarizes the

schema for placing patients in the five diagnostic categories. Clinical weakness, atrophy, and fasciculations are considered evidence of LMN pathology. Pathologic spread of reflexes, clonus, and pseudobulbar features are considered evidence of UMN pathology. Electrophysiologic findings can be used to both confirm LMN dysfunction in clinically affected regions and to detect LMN dysfunction in clinically uninvolved regions. Neuroimaging and clinical laboratory studies are used to exclude other conditions that may mimic ALS.

### Electrodiagnostic Testing

The various forms of MND, including SMA, Kennedy's disease, PMA, SALS, and FALS share several electrodiagnostic features but also differ in some aspects due to varying rates of disease progression (43). General EDX characteristics of MND include normal sensory nerve conduction studies (NCS), normal or low motor amplitudes depending on disease stage, and normal distal motor latencies and conduction velocities. However, with profound loss of motor amplitude, conduction velocities may drop as low as 25% below the lower limit of normal because of loss of the fastest conducting fibers. The needle electrode examination (NEE) reveals a decreased recruitment pattern, either normal size or large motor unit action potentials (MUAPs) with or without evidence of remodeling depending on the specific disease process, and abnormal spontaneous activity including positive sharp waves (PSWs), fibrillation potentials, fasciculations, and complex repetitive discharges (CRDs). The prominence of the various forms of spontaneous activity varies with the different forms of MND.

### Spinal Muscular Atrophies

The EDX features of the autosomal recessive SMAs I–IV are determined by the rate of anterior horn cell degeneration and the stage in the course of the disease. Sensory NCS are normal in all forms of SMA. Compound motor action potentials (CMAPs) are decreased in proportion to the degree of muscle atrophy. Motor velocities are most likely to be abnormally slow in SMA I because of the extensive loss of motor axons.

The most profound loss of MUAPs is seen in SMA I. With maximal effort, only a few MUAPs may fire at a rapid rate. Small MUAPs are common because reinnervation cannot compensate for the rapid loss of anterior horn cells. Myopathic appearing low amplitude, polyphasic, short duration units may also be seen because of muscle fiber degeneration. In the other types of SMA, one sees large amplitude MUAPs (up to 10 or 15 mV) because the number of fibers per motor unit increases as motor unit remodeling occurs. These large units also tend to be polyphasic with increased duration. Satellite potentials appear as remodeling occurs. Myopathic appearing MUAPs are also seen in some older patients with SMA III, and their etiology is not well understood.

On NEE in SMA I, fibrillation potentials and PSWs are diffuse and seen in many muscles, including the paraspinals. In the more chronic forms of SMA, fibrillation potentials and PSWs are even more common and increase in frequency as

age increases. CRDs are often seen in SMA II and III, and fasciculations are more common than in type I (44–46).

### Kennedy's Disease

Motor NCS abnormalities are similar to those seen in other forms of MND. Although patients generally do not have sensory complaints, absence or reduction of sensory nerve action potential (SNAPs) is a common finding (47,48). NEE shows large amplitude and duration MUAPs consistent with the rather indolent disease course. Fibrillation potentials and PSWs may be very prominent and present in all muscles examined. Fasciculation potentials are also abundant in limb, facial, and tongue muscles.

### Adult Nonhereditary MND

For many years, Lambert's criteria were the standard for the electromyographic (EMG) diagnosis of ALS (49,50). The following four criteria were required to make a definite diagnosis of ALS: (a) PSWs and/or fibrillation potentials in three of five limbs, counting the head as a limb. For a limb to be considered affected, at least two muscles innervated by different peripheral nerves and roots should show active denervation. (b) Normal sensory NCS. (c) Normal motor conduction studies; however, if the CMAP amplitude is very low, conduction velocity may drop as low as 70% of the lower limit of normal. (d) Reduced recruitment of MUAPs on needle exam. More recently, Cornblath et al. studied 61 patients with ALS and found that even with low CMAPs, motor distal latencies, and F wave latencies did not exceed 125% of the upper limit of normal, and motor conduction velocities did not fall below 80% of the lower limit of normal (51). The EDX findings in PMA are identical to those in ALS; the distinction between the two diagnoses is made by the presence or absence of UMN signs on physical examination. By definition, the EDX examination is normal in PLS. In PBP, active denervation is found only in muscles of the head and neck.

The EDX portion of the El Escorial criteria differs somewhat from Lambert's criteria and is generally more liberal. The revised El Escorial criteria allow EDX findings to be used to upgrade the certainty of a diagnosis from clinically possible ALS to probable ALS; this upgrading of the diagnosis is important because it often allows additional patients to participate in clinical trials which generally require a diagnosis of probable or definite ALS. The El Escorial EDX criteria state that active denervation must be present in two of the four spinal regions (bulbar, cervical, thoracic, and lumbar) to support a diagnosis of ALS. For the cervical or lumbosacral region to be counted, at least two muscles innervated by different nerve roots and peripheral nerves must have EMG changes. In the bulbar and thoracic regions, changes in one muscle are sufficient. Thus, a patient with active denervation in the left arm and thoracic paraspinals would meet the El Escorial criteria for an EDX diagnosis of ALS but not the Lambert criteria because only one limb is involved. On the other hand, a patient with denervation in the tongue and both arms would fulfill Lambert's criteria and the El Escorial criteria for ALS because three limbs and two regions are involved (bulbar and cervical). Early in the

progression of ALS, many patients with a suspected clinical diagnosis do not meet EDX criteria for a definite diagnosis. A repeat study several months later will often fulfill the EDX criteria for diagnosis.

NCS in ALS are characterized primarily by decreased CMAP amplitudes. The mild slowing of motor conduction velocity and the prolongation of F wave latencies are attributed to loss of the fastest conducting axons. An interesting phenomenon observed in many patients is that of the “split hand”; CMAP amplitudes are decreased to a greater extent on the radial side of the hand than on the ulnar side. CMAPs obtained from the abductor pollicis brevis and first dorsal interosseous are much lower than those obtained from the abductor digiti minimi. More than two stimulation sites should be used in the evaluation of motor nerves to exclude the presence of conduction block since multifocal motor neuropathy with conduction block is occasionally misdiagnosed as ALS. The ulnar nerve easily can be stimulated at the wrist, below the elbow, above the elbow, in the axilla, and in the supraclavicular fossa. In limbs with UMN signs, H-reflexes may be elicited from muscles in which they cannot normally be obtained. A few patients do have SNAP abnormalities, and the sympathetic skin response is absent in 40%, suggesting subclinical autonomic nervous system involvement (52). Repetitive stimulation studies may show a decrement in CMAP with stimulation at 3 Hz which is similar to that seen in myasthenia gravis. A decrement is especially likely to be detected in patients with rapidly progressing disease and in muscles with an abundance of fasciculations (43).

The NEE is the most important part of the EDX examination in cases of suspected ALS. Fasciculation potentials are seen in most patients with ALS, but they are not necessary to meet diagnostic criteria, and the presence of only fasciculations is inadequate as evidence of LMN involvement of a particular limb or region. The significance of fasciculations depends on the company they keep; they are pathologic only when accompanied by fibrillation potentials, PSWs, or recruitment pattern or MUAP size changes. In patients with advanced ALS, fibrillation potentials and PSWs are prominent in most muscles, but they may be sparse early in the course of the disease. Occasionally, CRDs and doublets or triplets are seen in patients with ALS, but these are not typical EDX findings in ALS. The thoracic paraspinals should be examined with a needle; they are not involved in tandem cervical and lumbar stenosis and can help exclude this as a diagnostic possibility. In addition, when the El Escorial criteria are employed, the finding of denervation in the thoracic and in either the cervical or the lumbar region is sufficient for a definite diagnosis, making examination of the tongue or facial muscles, which many patients find unpleasant, unnecessary. Although fasciculations and denervation of the tongue are considered almost pathognomonic for ALS, they are seldom found in patients who do not have clinical evidence of bulbar muscle involvement. The recruitment pattern is decreased in involved muscles. If the disease is progressing relatively slowly, MUAP amplitudes and durations become increased; but if the course is very rapid, denervation

outpaces reinnervation and enlarged MUAPs do not have time to develop. The density and distribution of fasciculations and fibrillations do not correlate with disease course or prognosis, and serial EDX examinations are not useful for monitoring disease progression once a definite diagnosis has been made.

Neurophysiologists have begun to explore the use of transcranial magnetic stimulation as a method of identifying subclinical UMN dysfunction. Results are contradictory with respect to the sensitivity and specificity of various findings as evidence of UMN dysfunction, and these techniques must be considered experimental at present. Abnormalities suggesting UMN pathology include a motor evoked potential (MEP) much lower in amplitude than the CMAP recorded from the same muscle, prolonged central motor conduction time, decreased MEP thresholds and silent periods early in disease, increased MEP thresholds in advanced disease, and decreased cortical representation of individual muscles (53–56).

### Neuroimaging

Imaging studies are used to exclude possibilities other than MND from the differential diagnosis. Magnetic resonance imaging (MRI) is the primary imaging modality used in the evaluation of patients with suspected ALS. Almost all patients should have an MRI of the cervical spine to rule out cord compression, a syrinx or other spinal cord pathology. The location of symptoms will dictate whether or not other regions of the spinal cord should be imaged. In patients presenting with the PMA phenotype, an MRI of the involved region of the spinal cord with gadolinium should be considered to look for a metastatic polyradiculopathy. In those presenting with bulbar symptoms, a brain MRI should be performed to rule out stroke, tumor, syringobulbia, etc.

Although MRI is generally not performed to confirm a diagnosis of ALS, a few associated abnormalities have been reported. Rarely, spinal cord and motor cortex atrophy is apparent. Corticospinal tract hyperintensity with T2 imaging has been observed in a few younger patients with a predominance of UMN signs (53).

### Laboratory Evaluation and Other Diagnostic Tests

In most neuromuscular clinics, a routine panel of laboratory tests is performed for all patients suspected of having ALS. The rationale behind performing this battery of tests is to assess the general health of the patient and exclude treatable conditions. The differential diagnosis, developed following the history and physical exam, may suggest that more specialized testing be performed. Additional tests may be warranted when the presentation is with the PMA, PLS, or PBP phenotype. When there is a family history of MND, genetic testing for FALS is performed.

### ALS CLINICAL TRIALS

Clinical trials play a crucial role in the development of new therapeutic agents. It is important to begin thinking about

what an appropriate trial would look like far in advance of actual study initiation. Decisions regarding dose, outcomes to be measured, and duration of treatment all may have a critical impact on whether a new agent is found to be efficacious. Many of these decisions depend on adequate preclinical data. In the absence of good preclinical data, trials may fail to show efficacy or even demonstrate harm to patients that could have been avoided. In recent years, much has been learned about pathogenic mechanisms of ALS, leading to a proliferation of new targets for disease modification. Mitochondrial dysfunction, glutamate toxicity, protein misfolding, and microglial activation are just a few mechanisms that have been proposed. For each proposed mechanism, pharmacological manipulation is possible. Targeted drug discovery programs can lead to new compounds, and reevaluation of existing drugs may lead to recognition of properties not previously investigated. Recently, a collaborative effort jointly funded by the National Institute of Neurological Disorders and Stroke (NINDS) and the Amyotrophic Lateral Sclerosis Association (ALSA) tested more than 1,000 available compounds in 29 different assays to determine activity against a variety of different aspects of neurodegeneration (57). Although the full result of this effort has not yet been published, individual laboratories have further investigated drugs identified by this screening program, with the first of these (ceftriaxone) having entered clinical trials in 2006. At this writing, there are at least nine different compounds either in human trials or about to be tested in humans. All of these compounds target different aspects of the neurodegenerative process.

Assuming that the maximum tolerated dose (MTD) has been established in experimental models, as well as a range of doses that show activity against the target disease mechanism, dose ranges in the initial studies on humans can be appropriately chosen. In ALS, this step has been problematic. For a number of compounds that have been previously studied in efficacy trials, the MTD has not been established. Thus, negative results have been reported for creatine and celecoxib, yet the lack of a known MTD leads to the question of whether higher doses of either creatine or celecoxib could have demonstrated efficacy (58,59). In other studies, attempts were made to study compounds at doses close to MTD, but lower doses were not studied as well. This may have contributed to the fact that patients treated with topiramate at 800 mg/day progressed faster than placebo patients, and may also account for similar results in the recently reported minocycline trial (60,61).

ALS presents some unusual challenges in terms of clinical trials. In diseases associated with markers of activity (i.e., CD4 counts or viral load in HIV), the effect of differing doses on these markers can be used to determine the dose choices for a phase III trial. In ALS, no such markers have been identified, so that attempts to gauge efficacy must be based on the outcomes typically employed in larger phase III trials. For this reason, the line between phase II and phase III trials is often blurred in ALS. Thus, decisions about dose are often made after phase II trials, so it is essential that multiple doses be evaluated. This has often not been done in phase II ALS trials, and

when dose ranging is done, it is often inadequate. For example, topiramate was tested in a phase II study at a dose of 800 mg/day (62). Although there was no statistically significant effect on mortality, treated patients lost an average of 10 lb more weight than placebo-treated patients and performed more poorly on functional and respiratory measurements (62). From assessment of adverse events, it was clear that at this dose, topiramate was quite difficult to tolerate, and the results reported could easily have been a function of patient's weight loss and other events.

## Outcome Measures

Given that there are no tissue-based biomarkers currently existing to determine drug activity in ALS, clinical assessment of efficacy is based on measurement of a variety of aspects of disease. The gold standard outcome for ALS trials currently remains survival. Survival is obviously clinically meaningful and straightforward to measure. There are several reasons, however, why other measures are being sought and why many current trials use outcomes other than survival. First, survival can be manipulated by many interventions that do not clearly alter the progression of underlying disease. Good nutrition and early use of percutaneous endoscopic gastrostomy (PEG) clearly prolong life (63). Respiratory support with noninvasive positive pressure ventilation (NIPPV) has been less well studied, but likely also prolongs life (64,65). Beyond these clearly defined interventions, there is emerging evidence that patients cared for at multidisciplinary ALS clinics have prolonged survival as compared to community-based controls (66,67). As these interventions may not be applied uniformly across all sites in a clinical trial, conclusions based on survival may be confounded by these variables. Many trials stratify along certain treatment variables, but stratification can reduce the power of a trial to find a significant drug benefit.

## PHARMACOLOGIC MANAGEMENT OF MND

### Riluzole

Despite clinical use for more than 14 years, riluzole, a 2-amino-6-(trifluoromethoxy) benzothiazole, remains the only Food and Drug Administration (FDA)-approved medication proven to slow the progression of ALS. Pharmacological mechanisms of riluzole include interference with *N*-methyl *D*-aspartate (NMDA) receptor-mediated responses, stabilization of the inactivated state of voltage-dependent sodium channels, inhibition of glutamate release from synaptic terminals, and activation of extracellular glutamate uptake. Riluzole has demonstrated neuroprotective effect in motor neuron cultures and SOD1G93A transgenic mice (68–79). A recent Cochrane Database Review concluded Riluzole 100 mg daily prolongs median survival by about 2 to 3 months based on analysis of four randomized controlled trials (75). Recent studies using large registries suggest a greater benefit, ranging from 4 to 20 months. Although American Academy of Neurology practice guideline recommends the use of Riluzole for nonventilated ALS patients, analysis of the

ALS CARE database found that 41% of the cohort was not prescribed this medication, largely due to the expense (80,81). The drug is generally well tolerated, with asthenia, nausea, and an increase in serum alanine aminotransferase the most common side effects (82). Liver function should be monitored during therapy.

Over the past 15 years, over 20 agents have been tested in Phase II and III clinical trials, and several additional trials are ongoing. None of these agents tested thus far has shown enough efficacy to warrant FDA approval for treatment of ALS. Some of these agents and trials are briefly discussed below.

## Experimental Therapies and Clinical Trials

### Growth Factors

Growth factors represent a large, heterogeneous group of endogenous polypeptides with varying physiological activity including cell signaling, cellular growth and differentiation, angiogenesis, regulation of inflammation, and antiapoptotic effect. Growth factor clinical trials to date have been disappointing. Treatment with subcutaneous recombinant human insulin-like growth factor-1 (rhIGF-1 or myotrophin) for 9 months slowed deterioration on the Appel ALS rating scale in a multicenter, North American trial but not in a similarly designed European study which may have been statistically underpowered (83,84). A 2007 Cochrane Database Review concluded that available data were insufficient to render definitive assessment of rhIGF-1 as a clinical therapy for treatment of ALS (85). A third phase III study is currently complete and results are pending. Neurotrophins, including brain derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), and glial cell line–derived neurotrophic factor (GDNF) and oral xaliproden which has neurotrophic-like activity, have failed to demonstrate benefit in human clinical trials (86–90). Vascular endothelial growth factor (VEGF), erythropoietin (EPO), and hepatocyte growth factor (HGF) slow motor neuron deterioration *in vitro* and prolong survival in transgenic ALS rodent models but, to date, no human trial data has been reported (91–100).

### Antiepileptics and Glutamate Reducing

The cephalosporin antibiotics were identified via an National Institutes of Health (NIH) sponsored high throughput drug screening program as potentially beneficial for slowing progression of ALS. Ceftriaxone increased both brain expression of astroglial glutamate transporter GLT1 and its biochemical and functional activity, and delayed loss of neurons and muscle strength, associated with increased mouse survival. Its CNS penetration and long half-life are well known, obviating the need for extensive safety trials (101). A large multicenter clinical trial is currently ongoing.

Memantine is a noncompetitive NMDA receptor antagonist. It has been shown to protect neurons against NMDA- or glutamate-induced toxicity *in vitro*. Treatment of SOD1G93A mice significantly delayed disease progression and increased life span (102). Safety studies are completed, and efficacy studies are enrolling patients (Clinicaltrials.gov NCT00409721 & NCT00353665).

*N*-acetylated  $\alpha$ -linked acidic dipeptidase (NAALADase) inhibition decreases extracellular excitotoxic glutamate and increases extracellular *N*-acetylaspartylglutamate (NAAG), both of which lead to increased neuroprotection (106). Selective glutamate carboxypeptidase (GCP) II inhibitors demonstrated efficacy in models of stroke, ALS, and neuropathic pain. GCP II inhibition may have benefits over existing glutamate-based neuroprotection strategies, being selective for excitotoxic-induced glutamate release, with potentially fewer side effects (103). Phase I studies showed GCP II inhibition to be safe and well tolerated by healthy volunteers and diabetic patients (104).

ONO-2506 is an enantiomeric homologue of valproate that restores disturbed astrocyte functions (105). Subgroup analysis of a phase II trial suggested slowed respiratory deterioration in patients with shorter duration disease (August 10, 2005 Public Relations Ono Pharmaceutical Co., Ltd). A phase III trial of valproate has completed enrollment (Clinicaltrials.gov NCT00403104).

Talampanel is a noncompetitive modulator of  $\alpha$ -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) glutamate receptors which crosses the blood-brain barrier. It prolonged SOD1G93A mouse survival. ALS functional rating scale (ALSFERS) and tufts quantitative neuromuscular exam (TQNE) scores declined at a slower rate in a 9-month phase II study of talampanel in 60 patients with ALS (106).

### Antiapoptosis and Anti-Inflammatory

Tamoxifen inhibits protein kinase C, and may reduce inflammation in the spinal cord of patients with ALS (107). Tamoxifen extended survival in a virally induced ALS mouse model, although this was a very underpowered study (108). A tetracycline antibiotic, minocycline inhibits caspase activity by preventing its up-regulation, thereby decreasing motor neuron death. It also reduces glutamate-induced activation of microglia (109). Minocycline prolonged survival in mouse models of Huntington's disease and FALS (110). In a controlled trial of minocycline (400 mg/day,  $n = 412$ ), ALSFERS-R, patients in the treatment group declined faster over a 9 month treatment period. There was also a trend toward faster decline in strength and pulmonary function and increased mortality (111).

TCH386 (dibenz[b,f]oxepin-10-ylmethyl-prop-2-ynylamine, hydrogen maleate salt) prevents both the apoptotic increases and the nuclear accumulation of the glycolytic enzyme, glyceraldehyde 3-phosphate dehydrogenase (GAPDH). TCH386 (CGP 3466B) slowed disease progression in a murine model (112). In a controlled study of 554 subjects, TCH386 was evaluated at four different doses, and patients actually did worse than those receiving placebo (113).

### Antioxidants

Overexpression of heat shock protein conferred protection from ischemic injury in mammalian brain (114). Arimoclomol, a coinducer of heat shock proteins, delayed progression of ALS in a mouse model (115). A dose ranging phase II study is completed and a phase III study is planned. Mitochondrial dysfunction in ALS may be aided by CoQ10 (116). In SOD1G93A

transgenic mice, low-dose coenzyme Q10 prolonged median survival by 4.4% (117). Phase II studies in humans suggested that doses as high as 2,700 mg/day had no greater efficacy than placebo (118–120).

A study of vitamin E versus placebo in patients on riluzole yielded no difference in survival, although there was a tendency to remain longer in the milder states of ALS with vitamin E (121). Five grams per day of vitamin E was well tolerated in a phase III trial. However, no significant difference in survival was noted between treatment groups (121,122).

### Immunomodulatory/Anti-inflammatory

The anti-inflammatory Celecoxib, a selective cyclooxygenase-2 (Cox-2) inhibitor which demonstrated neuroprotective effects and prolonged longevity in SOD1G93A mice, failed to show benefit on strength measures or survival at 800 mg/day dosing in a large, randomized, placebo-controlled trial (123).

Creatine has neuroprotective effects through blockade of the mitochondrial membrane pore and as an antioxidant, but failed to show benefit in two large, randomized controlled trials (124,125).

Copolymer-1 (copaxone) induces a neuroprotective T cell-mediated response. ALS mice treated with copolymer-1 experienced delayed disease onset, improved motor function, and extended survival (126). Thalidomide and its analog lenalidomide, both inhibit the expression of TNF- $\alpha$  and other cytokines by destabilizing their mRNA, thus reducing inflammation. Treatment with either thalidomide or lenalidomide attenuated weight loss, enhanced motor performance, decreased motor neuron cell death, and significantly increased the life span in G93A transgenic ALS mice (127).

### Neurodegeneration

Lithium prevents neurodegeneration by promoting autophagy, through inhibition of inositol monophosphatase, rescues spinal cord mitochondria, and facilitates the clearance of  $\alpha$ -synuclein, ubiquitin and SOD1. It delayed disease onset and progression in G93A transgenic mice and increased survival and slowed progression in humans over 15 months compared to controls in a small study with somewhat atypical slowly progressing patients (128). Larger trials are currently underway.

ALS progression is complex and likely due to cellular dysfunction at multiple levels, including mitochondrial dysfunction, glutamate excitotoxicity, oxidative stress, axonal dysfunction, reactive astrogliosis, and mutant SOD1 expression, therefore, treatment must provide neuronal protection from multiple insults. A significant amount of ALS research focuses on growth factor-based therapies. Growth factors including insulin-like growth factor-I, VEGF, BDNF, and GDNF exhibit robust neuroprotective effects on motor neurons in ALS models. Issues concerning growth factor delivery, stability, and unwanted side effects slow the transfer of these treatments to human ALS patients. Stem cells represent a new therapeutic approach offering both cellular replacement and trophic support for the existing population. Combination therapy consisting of stem cells expressing beneficial growth factors may

provide a comprehensive treatment for ALS and there are a number of animal studies which support this (129–137).

### Innovative Approaches

Extensive ineffective clinical trials in ALS involving various subcutaneously and orally administered medications have been disappointing, which has led to novel approaches to drug delivery and nonpharmacologic forms of treatment. Gene therapy approaches and RNA interference are being explored for patients with SOD1 mutations. There is also a great deal of interest in stem cell transplantation, but it is not yet available in scientifically sound human trials. In feasibility and safety studies of intraspinal cord implantation of autologous mesenchymal stem cells (MSCs), there were no convincing clinical benefits (138,139).

### Cannabinoids (Cannabis)

Studies done in animal models of glutamate-induced neurotoxicity have shown that cannabinoids (the active ingredients in cannabis, aka, marijuana) afford protection against oxidative damage induced by free radicals produced by glutamate (140–148). Administration of delta-9-THC both before and after the onset of ALS symptoms slowed disease progression and prolonged survival in animals compared to untreated controls (149). Other trials in animal models of ALS have also shown that naturally occurring and synthetic cannabinoids slow down the progression of ALS (150–152). In addition to the neuroprotective effect, patients also report that cannabis helps in treating symptoms of the disease, including alleviating pain and muscle spasms, improving appetite, diminishing depression, and helping to manage sialorrhea (excessive drooling) by drying up saliva in the mouth (153,154). Further investigation at both the basic science and clinical levels into the usefulness of cannabinoids in treating ALS is warranted.

## REHABILITATION AND PALLIATIVE CARE

Although currently incurable, adult MNDs are not untreatable. The goals of rehabilitation and palliative care in these patients are to maximize functional capacities, prolong or maintain independent function and locomotion, inhibit or prevent physical deformity, and provide access to full community integration with good quality of life. In ALS, this also includes addressing end-of-life issues and assuring that the patient has a comfortable death.

The comprehensive management of all of the varied clinical problems associated with adult MNDs is an arduous task. For this reason, the multidisciplinary approach is much more effective and takes advantage of the expertise of many clinicians, rather than placing the burden on one. Management is best carried out by a team consisting of physicians, physical, occupational, and speech therapists, social workers, vocational counselors, and psychologists, among others. Ideally, due to the significant mobility problems associated with these diseases, the physician and all the key clinic personnel should be

available at each visit. Tertiary care medical centers in larger urban areas can usually provide this type of service. This may be an independent clinic or sponsored by one or more of the consumer-driven organizations sponsoring research and clinical care for people with MNDs, including the Muscular Dystrophy Association (MDA), or the ALSA.

The rehabilitative and palliative care strategies discussed in this section may be applied to any form of adult MND, but the focus of this discussion is primarily on ALS.

Initial confirmation of the diagnosis is critical and is a primary responsibility of the consulting neurologist. Due to the ominous prognosis of ALS, a confirmatory second opinion should always be sought. A physiatrist is well suited to direct the rehabilitation team and oversee a comprehensive, goal-oriented treatment plan (155,156). Irrespectively, a single primary physician who coordinates all rehabilitative care should be identified early in the process, either a specialist or the family physician if he or she is willing and knowledgeable of the disease.

At initial evaluation, the patient should be thoroughly educated about the expected outcome and what problems may be encountered. Enrollment in an experimental drug trial, as discussed previously in this chapter, should be encouraged and facilitated. It not only furthers science but provides some hope for the patient and ensures frequent follow-up. The physician should then assess the patient's goals and orchestrate a rehabilitative and ultimately a palliative program that matches those goals. In ALS, palliative care should be aimed at maximizing a patient's comfort and quality of life but not necessarily extending their life.

## **Spectrum of Clinical Problems and Treatment Paradigms**

### **Weakness and Fatigue**

Skeletal muscle weakness is the sine qua non of all adult MND, including ALS, and is the ultimate cause of the majority of clinical problems associated with these diseases. There have been precious few studies of exercise in ALS. However, in other more slowly progressive neuromuscular diseases, a 12-week moderate resistance (30% of maximum isometric force) exercise program resulted in strength gains ranging from 4% to 20% without any notable deleterious effects (157). Nonetheless, in the same population, a 12-week high-resistance (training at the maximum weight a subject could lift 12 times) exercise program showed no further added beneficial effect compared to the moderate resistance program, and there was evidence of overwork weakness in some of the subjects (157). However, due to the active, ongoing muscle degeneration in most cases of ALS, and to a lesser extent in SMA and SBMA, the risk for overwork weakness is great and exercise should be prescribed cautiously and with a common sense approach. Patients should be advised not to exercise to exhaustion, which can produce more muscle damage and dysfunction (158). Patients participating in an exercise program should be cautioned of the warning signs of overwork weakness, which include feeling weaker rather than stronger within 30 minutes post exercise

or excessive muscle soreness 24 to 48 hours following exercise. Other warning signs include severe muscle cramping, heaviness in the extremities, and prolonged shortness of breath (158).

Given the lack of any apparent contraindication, aerobic exercise training is recommended for patients with ALS as long as it can be performed safely without a risk of falling or injury. In addition to the physical benefits, this form of exercise often has a beneficial effect on mood, psychological well-being, appetite, and sleep. Pool therapy is often an ideal place for patients with ALS to do aerobic exercise, which can be as simple as walking in the water, with the water at midchest height. This is best done in a therapy pool with a flat, uniform depth floor that is heated to 92°F to 95°F. The warmth of the water will help reduce spasticity and facilitate movement. Other interventions might include low impact aerobic exercise such as walking, or stationary bicycling to improve cardiovascular performance and increase muscle efficiency, and thus help fight fatigue (158). Fatigue in ALS is multifactorial and is due, in part, to impaired muscular activation (159,160). Other contributing factors include generalized deconditioning from immobility and clinical depression. Aerobic exercise not only improves physical functioning but is beneficial in fighting depression and improving pain tolerance.

Although there have been few well-controlled studies looking at exercise-induced strength gains in the ALS population, a recent Cochrane review looked at this. Studies in randomized or quasi-randomized controlled trials of people with a diagnosis of definite, probable, probable with laboratory support, or possible ALS, as defined by the El Escorial criteria were recently published (161). This included progressive resistance or strengthening exercise and endurance or aerobic exercise. The control condition was no exercise or standard rehabilitation management and the primary outcome measure was improvement in functional ability, decrease in disability, or reduction in the rate of decline as measured by a validated outcome tool at 3 months. Secondary outcome measures were improvement in psychological status or quality of life, decrease in fatigue, increase in or reduction in the rate of decline of muscle strength (strengthening or resistance studies), increase in or reduction in the rate of decline of aerobic endurance (aerobic or endurance studies) at 3 months, and frequency of adverse effects. Two randomized controlled trials met the inclusion criteria. The first examined the effects of a twice-daily exercise program of moderate load, endurance exercise versus "usual activities" in 25 people with ALS (162). The second examined the effects of thrice weekly moderate load and moderate intensity resistance exercises compared to usual care (stretching exercises) in 27 people with ALS (163). After 3 months, when the results of the two trials were combined, there was a significant weighted mean improvement in the ALSFRS measure of function in the exercise compared with the control groups (3.21, 95% confidence interval 0.46 to 5.96) in favor of the exercise group. No statistically significant differences in quality of life, fatigue, or muscle strength were found.

### Respiratory System Involvement in ALS and SMA

Neither ALS nor SMA has any direct effect on the lung. However, the mechanical respiratory system is significantly involved in all of these MNDs, although least often in later onset SMA III. For the purposes of this discussion, we focus primarily on ALS, although all of the modalities discussed herein are applicable to all of these disorders. ALS affects all of the major muscle groups of the mechanical respiratory system: (a) upper airway muscles (abnormal swallowing and cough); (b) expiratory muscles (inadequate cough) and inspiratory muscles (inadequate maintenance of ventilation). Therefore, all patients with ALS are at significant risk of respiratory complications, and the leading cause of death in this population is respiratory failure.

Cough is an essential airway protection reflex. Particles are expelled from the airway through a complex set of nerve and muscle responses to cough stimulation through receptors located predominantly in the upper airway (164–167). Cough receptor stimulation results in inhalation to approximately 60% of maximum vital capacity (inspiratory phase). The glottis then closes and the abdominal muscles contract, resulting in markedly elevated intrathoracic pressures without airflow (compressive phase). The glottis opens shortly thereafter and gas is propelled through the airways at very high velocities, resulting in airway clearance (expiratory phase). The individual with ALS may experience cough impairment in any one or all three of the stages of cough including reduction in the inspired volume due to diaphragm weakness, inability to close the glottis completely during the compressive phase due to bulbar muscle dysfunction, and inability to compress and expel intrathoracic gas because of expiratory muscle weakness. There appears to be a threshold of expiratory muscle strength loss necessary to reduce cough force. Maximal expiratory pressure (MEP), a commonly used clinical measure of expiratory muscle strength, does not correlate well with the presence or absence of cough generation (164). Inspiratory muscle strength also does not correlate well with cough generation (164). Endoscopic evaluation of ALS patients with respiratory symptoms reveals obvious glottic dysfunction (168). Some have suggested that measurement of peak cough flow (PCF) is an effective noninvasive assessment of cough function (169). In our experience, a measured PCF of less than 160 L/minute during acute respiratory illness and 270 L/minute in the absence of respiratory illness is associated with poor cough and a high risk of respiratory infection.

ALS often effects the inspiratory muscles including the diaphragm and external intercostal muscles. This leads to a reduction in respiratory muscle strength, RLD, and ultimately, carbon dioxide retention and frank respiratory failure. In rare cases, respiratory muscle dysfunction leading to respiratory failure may be the presenting clinical picture for the ALS patient. Usually, the symptoms of respiratory muscle insufficiency such as dyspnea occur gradually over time and may defy diagnosis. Pulmonary function testing is invaluable in assessing the level of respiratory impairment, following disease progression as

well as assessing prognosis in ALS. Respiratory muscle strength measures do appear to correlate with dyspnea in ALS patients even when there is near normal vital capacity (169–171). In patients where oral bulbar weakness may limit the ability to accurately measure maximum inspiratory pressure by mouth, sniff nasal inspiratory pressure (SNIP) has been found to be a reliable alternative (171). Both maximum inspiratory pressure (MIP) and SNIP may be inaccurate measures of inspiratory muscle strength when significant bulbar weakness effects the test maneuver due to inadequate oral seal or upper airway collapse.

Nocturnal hypoventilation and sleep disordered breathing are a common problem for patients with ALS. This can occur even when respiratory muscle function is only mildly affected and daytime gas exchange remains normal (172,173). Neural output to the respiratory muscles decreases during sleep. Even mild muscle weakness coupled with the normal decreases in ventilatory drive can result in nocturnal hypoventilation and disturbed sleep architecture. Symptoms and signs of nocturnal hypoventilation can manifest both at night and during the day. Nighttime symptoms include air hunger, observed apneas, orthopnea, cyanosis, restlessness, nightmares, and insomnia. Daytime findings include excessive sleepiness, morning headaches or drowsiness, and later in the course, polycythemia and pulmonary hypertension. The health care provider should be vigilant for these symptoms. Sleep studies can be very helpful in elucidating sleep disturbed breathing in these patients if doubt remains.

Hypercarbia as well as atelectasis can lead to lower than expected arterial oxygen levels, but primary oxygenation problems are not common in ALS, except in the final stages when pneumonia intervenes. Oxygen as a primary therapy for respiratory insufficiency is not recommended. However, oxygen therapy in an attempt to relieve dyspnea in the hospice setting may be appropriate.

### Managing Respiratory Problems in ALS

The respiratory specialist is integral to the care of the ALS patient because of the multiple effects of the disease on the respiratory system. Frequent monitoring of pulmonary function gives valuable information on prognosis as well as input into the timing of interventions and discussions of long-term mechanical ventilation. We have found that the most efficient way of delivering health care to these individuals at our institution is through a multidisciplinary clinic that involves care providers from rehabilitation medicine, neurology, pulmonary medicine, respiratory therapy, as well as speech-language pathology. The following discussion focuses on the monitoring and management of respiratory issues related to ALS, as outlined in Figure 28-6.

The risk of aspiration and development of pneumonia in patients with ALS is due primarily to problems with upper airway function and cough. Pharyngeal and laryngeal muscle dysfunction can lead directly to aspiration of oral contents into the lungs. Other than surgical diversion of the airway, no treatment directly aimed at the laryngeal and glottic function

**FIGURE 28-6.** Algorithm for the management of respiratory symptoms in ALS.

is available. However, reduction of the amount of salivary secretions is possible through the use of a number of medications and modalities, including anticholinergic medicines and dietary manipulation such as avoiding dairy products which thicken the secretions. Teaching proper swallowing technique to avoid aspiration is also helpful. This involves performing a chin tuck and using straws, thickening liquids, concentrating on eating during mealtime (no TV, reading, etc.), and maintaining hydration with at least two quarts of water per day. In addition, when ALS patients develop significant dysphagia and aspiration with solids or liquids, many experts recommend

early placement of a PEG tube (174). This may prevent large volume aspiration and is associated with improvement in hydration and nutritional status.

Cough function, which is dependent in larger part in expiratory muscles, can be mechanically assisted when adequate bulbar function exists. When PCF drops below 270 L/minute, we carefully evaluate potential interventions to improve cough function. Those interventions may include teaching the caregivers manually assisted cough and the Heimlich maneuver. Inspiratory-related cough weakness can be supported by the use of manual insufflation. A one-way valve mouthpiece

circuit combined with a self-inflating resuscitator bag can be used to insufflate the lungs by applying a series of breath stacking maneuvers. When bulbar function is good but the patient has significant expiratory muscle weakness, mechanical insufflation (*Cough Assist Device*, Respironics Inc., Murrysville, PA) can be used to augment cough function. This device mimics the normal cough and has been shown to be helpful in patients with ALS and other neuromuscular diseases. Both mechanical pressure targeted insufflation and manual hyperinflation may also be beneficial to neuromuscular patients in maintaining lung compliance, decreasing the work of breathing, and managing atelectasis. Hyperinflation maneuvers can be administered by using either manual hyperinflation or by mechanical insufflation using the cough assist device.

Progressive inspiratory muscle weakness in ALS inevitably leads to carbon dioxide retention and hypercarbic respiratory failure. In fact, the major cause of death in ALS is respiratory failure. Predicting when respiratory failure will occur in the patient with ALS is important in order to plan appropriate clinical interventions and to help patients and their families address crucial decisions concerning long-term mechanical ventilation and end-of-life issues. Unfortunately, accurately predicting impending respiratory failure is a difficult task. Assessing symptoms of respiratory insufficiency such as dyspnea and orthopnea on each visit is important. Objective measurements of pulmonary function can be helpful but are not entirely predictive of either impending respiratory failure or death. We rarely obtain arterial blood gases as  $\text{PaCO}_2$  can be maintained until immediately prior to respiratory failure. Although most authors agree that although it is impossible to accurately predict the lifespan of any given individual with ALS, severe restrictive disease with an forced vital capacity (FVC) of less than 50% should prompt careful discussions with the patient concerning medical interventions in the event of respiratory failure (164). The frequency at which FVC measurements should be taken has not been established but every 3 months appears to be a reasonable time frame. This measurement can easily be performed in clinic with portable spirometry equipment. FVC should be measured in both the seated and the supine positions as it is often lower supine, which contributes to nocturnal hypoventilation. Patients with oral muscle weakness may need to perform spirometry maneuver through an air cushion facemask in order to obtain reliable measurements. Bulbar-related upper airway obstruction that results in an uneven forced expiratory flow volume pattern can portend a poor prognosis related to airway protection, cough effectiveness, and tolerance of and benefit from noninvasive respiratory therapies.

Mechanical ventilator support with NIPPV has been shown to be effective in improving both quality and duration of life (165,172,175). Improvements in cognitive function have been shown in ALS patients receiving nocturnal NIPPV (176). Recently, a randomized controlled trial of noninvasive ventilation was done in a cohort of ALS patients, measuring both survival and quality of life (175). Ninety-two patients were assessed every 2 months and randomly assigned to noninvasive ventilation or standard care when either orthopnea

developed with a maximum inspiratory pressure of less than 60% of predicted, or when symptomatic hypercarbia occurred. NIPPV improved quality of life and survival in all patients without bulbar symptoms as well as in a subset of patients with mild bulbar symptoms. In patients with more severe bulbar symptoms, NIPPV produced some improvement in quality of life but did not improve survival.

The Practice Parameters of the American Academy of Neurology suggests that all patients with ALS and respiratory symptoms or an FVC less than 50% predicted should be offered the use of NIPPV (177). NIPPV is usually initiated at night because of high frequency of sleep-disordered breathing. Sleep studies may be helpful if symptoms are unclear and FVC greater than 50%, although they are not necessary to initiate treatment. Patients will often progress to using NIPPV during the day, as their disease progresses, and we have had several patients who have used this modality for 24 hours/day. Portable daytime NIPPV can be most easily provided by using a bilevel pressure ventilator in conjunction with a less obtrusive interface, either a nasal cannula or nasal pillow interface. A small subset of patients with slow progressing limb onset disease and no bulbar symptoms may benefit from portable daytime mouthpiece ventilation (MPV). Portable MPV can be supported using a bilevel pressure ventilator but is most effectively administered using a pressure triggered volume-cycled home ventilator. The benefits of MPV include progressive ventilatory support as well as sigh and cough augmentation by the use of breath stacking maneuvers. Unfortunately, NIPPV is only a temporizing measure. Most patients with ALS will at some point develop bulbar symptoms that are severe enough that they will be unable to continue use of NIPPV because of aspiration pneumonia or failure of NIPPV to ventilate the patient effectively despite 24 hour/day use. At this point, consideration for invasive ventilation may be the only option for continued survival.

Invasive ventilation involves placement of tracheostomy or laryngeal diversion for direct airway access and use of a small usually volume-cycled home ventilator. A laryngeal diversion (laryngotracheal separation) is an alternative procedure where the proximal trachea is either oversewn or hooked side on end into the esophagus and the distal trachea is brought out through a stoma in the neck. This procedure has the advantage of completely preventing aspiration although phonation will no longer be possible (167). Tracheostomy is clearly a life-prolonging intervention and patient survival may extend indefinitely. Unfortunately, invasive ventilation has no effect on the progression of the disease and patients can develop complete paresis of all muscles including the extraocular muscles and develop a “locked-in” syndrome in which no communication is possible. The costs to patients and families both in financial and emotional terms are significant (178). Family members provide much of the care for these patients at home and may have to relinquish employment outside the home to do so. Despite this, many patients report a good quality of life while receiving mechanical ventilation with ALS (164). Most patients who undergo invasive mechanical ventilation do so in

the setting of emergent hospitalization without having planned in advance for this eventuality. Openheimer reviewed experience with 50 ALS patients on invasive mechanical ventilation and found that only four (8%) of the patients had chosen tracheostomy in advance, prior to acute respiratory failure and emergent intubation (179). Few ALS patients have advanced directives or living wills in place at the time when respiratory failure occurs. Benditt et al. have developed an instructive advanced directive that we have found particularly helpful in assisting discussions of mechanical ventilation and end-of-life issues in patients with ALS (178). Few patients in the United States seem to choose invasive mechanical ventilation as an option. This may be due to a number of factors including patient expectation of reduced quality of life, physicians not offering this as a medical option, the exorbitant costs of mechanical ventilation (estimates of \$15,000/month), and unavailability of family members to assist in patient care. The frequency of mechanical ventilation use in ALS varies worldwide from almost never (United Kingdom) to up to 48% (Japan) (180). This appears to be due to both cultural views of ALS as well as financial and structural differences in health care systems.

### Dysphagia and Nutrition

Patients with ALS frequently develop bulbar muscle dysfunction due to motor neuron involvement in the brainstem. Dysfunction of the lips, tongue, and pharyngeal and laryngeal muscles can result in an increased risk of aspiration as well as difficulty with generating adequate glottic closure for effective cough function. Swallowing may be impaired and ingesting adequate nutrition can be trying for the patient and family alike. Choking episodes are common and may even be triggered by saliva. Secretion management is a particularly difficult issue, as secretions may become viscous due to inadequate hydration. Sialorrhea (drooling) is due to inadequate handling of secretions rather than the amount of secretions as, in fact, salivary secretions in ALS appear to be less than in unaffected individuals (177). Malnutrition due to inadequate protein-calorie intake can occur and rapid weight loss should signal the clinician to carefully assess the swallowing mechanism (177). We have found referral to a speech and swallowing clinic to be very helpful in diagnosing swallowing and airway protection problems as well as instructing patients and their families in steps that they can take to reduce the risk of aspiration.

Most ALS patients without supplemental feeding through a percutaneous feeding tube will be deficient in energy intake (181,182). Both muscle and fat mass tend to decrease with disease progression. In addition, some patients become hypermetabolic; the etiology of this change in metabolism is not entirely clear, but it may be related to increased respiratory effort. Inadequate nutrition is concerning because it fosters greater muscle catabolism and may increase fatigue. Causes of malnutrition include arm weakness and inability to feed oneself, the time required to eat, and depression, in addition to bulbar muscle dysfunction and dysphagia. In a prospective study of

French patients with ALS, those who were malnourished had a 7.7-fold increased risk of death (183).

An algorithm for the management of dysphagia is shown in Figure 28-7. Dysphagia can initially be managed by instruction in compensatory strategies such as a double swallow, chin tuck, and head turning. Dietary modification such as thickening of liquids, moistening solids, and modifying temperature and texture may be helpful. Patients can often maintain nutrition orally by adding high-calorie liquid supplements to their diet.

When nutrition cannot be maintained orally, either partial or complete nutritional support may be provided via a feeding tube. In the past, most centers used PEG tubes, but many centers are now using radiologically inserted gastrostomy (RIG) tubes. RIG tubes seem to be easier and safer to insert in patients with low vital capacities (181,182). Indications for PEG or RIG include aspiration pneumonia, loss of greater than 10% of body weight, and/or the impairment of quality of life due to the time required to maintain nutrition orally. Feeding tube placement stabilizes weight and prolongs survival (177).

### Dysarthria

Dysarthria in ALS does not respond well to conventional articulation training. However, some adaptive strategies such as maintaining a slow speaking rate with an emphasis on increasing the precision of speech production may be helpful and can be taught by a speech-language pathologist. As the disease progresses, dysarthria should be approached by prescribing communicative aids, rather than traditional ongoing speech therapy. An alphabet supplementation or word board works well early on when patients still have reasonable arm function. After that, developing yes/no or other binary commands with eye-gaze systems may be used, particularly if the patient is using mechanical ventilation. There have been major recent advancements made in devices such as speech synthesizers or multipurpose, multiaccess, computer-based augmentative communication systems. Although expensive, these devices greatly enhance the patient's ability to communicate when they can no longer phonate. These types of devices may often be borrowed or rented from assistive technology centers which are often found at tertiary care medical centers.

### Spasticity

Spasticity in ALS is probably induced both at the motor cortex and at the spinal cord level. The gamma-aminobutyric acid (GABA) analog baclofen acts to facilitate motor neuron inhibition at spinal levels and is the agent of choice. Initial doses are 5 to 10 mg two to three times a day, titrating up to doses of 20 mg four times a day. Occasionally, higher doses (up to 160 mg/day) are more effective but caution is advised. Side effects include weakness, fatigue, and sedation. An intrathecal baclofen pump may be beneficial to some patients with MND. Tizanidine, an alpha-two agonist similar to clonidine, inhibits excitatory interneurons and may also be helpful. Dosing range is 2 to 8 mg three to four times a day, with a

This may be helped by a soft cervical collar, a Freeman or Headmaster type collar, which is a wire frame collar with padding over the pressure points.

Wheelchairs should have adequate lumbar support and good cushioning (gelfoam). The chair should be properly fitted to avoid pressure ulcers and inadequate support for the spine. Simply giving the patient a prescription for a wheelchair often results in the patient receiving a standard manual chair that does not fit properly; therefore, a team approach with physical and/or occupational therapists and the durable medical equipment (DME) provider is a much more beneficial approach. A power wheelchair, although expensive, can be justified since it will help prolong independent mobility and thus markedly improve quality of life. A good pressure relieving mattress (air or dense foam) should be used on the bed at home, along with foam wedges to facilitate proper positioning. This will help prevent pressure ulcers and contractures. Daily passive and active-assisted range of motion is critical. Maintaining mobility and functional independence as long as possible will have positive physical as well as psychological benefits. Ankle-foot orthoses molded in the neutral position may prolong ambulation and decrease the risk of injury if there is unilateral or bilateral foot drop. Wheeled walkers (rollator style in particular) or quad (four point) canes may also help, depending on the pattern of weakness. Other useful equipment includes hand-held showers, bath tub benches, grab bars, raised toilet seat, hospital bed, commode chair, activity of daily living (ADL) aids (sock aid, grabbers, etc.), and wheel chair ramps. An occupational therapist will help define which, if any, of these devices will be useful to the patient. Other simple suggestions such as moving the patient's bedroom to the first floor, removing any loose rugs, or covering slippery floors, are helpful and can be made during an in-home evaluation by the therapist.

Pharmacological management of pain in ALS includes the use of nonsteroidal anti-inflammatory (NSAID) medication, particularly if there is evidence of an active inflammatory process such as tenosynovitis or arthritis. Regular dosing of acetaminophen (1,000 mg every 6 hours) may be used along with an NSAID or alone if NSAIDs are not tolerated. Tricyclic antidepressants and anticonvulsant (membrane stabilizing) drugs such as Lyrica (pregabalin) or Neurontin (gabapentin) can sometimes be helpful for pain, particularly if there is a neuropathic component. Neurontin also has the potential added benefit of antispasticity properties. Narcotic medicine should be reserved for refractory pain. Concern for narcotic addiction is pointless in a terminal disease and the medications should be given on a regular dosing schedule and titrated to the point of comfort (182). Concomitant use of the antiemetic, antihistamine hydroxyzine (Vistaril) given along with the narcotic will enhance the effectiveness (i.e., 30 mg codeine plus 50 mg hydroxyzine every 6 hours p.r.n or scheduled depending on pain severity). Unlike narcotic medications, hydroxyzine is not a cortical depressant but does have direct skeletal muscle relaxant and analgesic properties and is known to potentiate the analgesic effect of narcotic

medication, although the exact mechanism is unknown (188). Combination elixirs can be prepared by the pharmacy for ease of administration. Oral or sublingual morphine (Roxanol), 10 to 30 mg every 4 hours, is also effective for comfort care and may help relieve "air hunger" in the terminal stages of the disease. Another option is taking the total dose of immediate release morphine required to alleviate pain and giving half of that every 12 hours in a controlled-release preparation such as MS Contin. Intramuscular delivery route should be avoided due to muscle wasting. Fentanyl or morphine patches may deliver inconsistent dosing, particularly if there is excessive perspiration. A patient-controlled analgesic (PCA) pump mechanism may not work in advanced stages of ALS due to inability of the patient to control the delivery. The main problems with narcotic medication in ALS are respiratory depression and constipation. These side effects may be quite acceptable in the final phases of life when respiratory insufficiency or severe pain requires increased doses of narcotics and/or benzodiazepines. In states where it is legal to do so, cannabis (marijuana) should also be considered as it has been shown to be effective in managing many of the symptoms of ALS, including pain, muscles spasms, loss of appetite, secretion control, and depression (153,154). Cannabis has an advantage of opiates in that it does not cause respiratory depression, constipation, or loss of appetite (154).

### End-of-Life Issues

ALS is a disease that poses some unusual ethical and humanitarian considerations. Although it is considered a fatal condition, unlike most cancers or other grave, incurable illnesses, it may take years to die from it, even though the disease continues to debilitate the person in the process. Thus, the patient with ALS has much time to think about the inevitability of the disease and what choices he or she wants to make in the terminal stages of the disease.

Despite the most aggressive treatment available, ALS will progress. Early in the disease, a social worker should be consulted to help arrange durable power of attorney to a responsible family member, usually the spouse. In most states, this can be done by a paralegal for a nominal fee. A Living Will should then be drafted which clearly outlines the patient's wishes regarding extent of medical intervention desired (178). This is particularly important with respect to entering hospice level care. Presumably, by the time hospice level care is being considered, the patient has had ample time for grieving, anger, and ultimately, acceptance of his or her fate. However, in our experience, many ALS patients still are hesitant about enrolling in hospice since it implies that the disease has reached end stage (189,190).

The patient should also be referred to a support group. The most prominent consumer-driven organizations facilitating support groups for people with ALS are the MDA and the ALSA. Local branches may be contacted to locate the nearest ALS support group. Support groups are often a great resource, not only for psychological support but for problem solving and equipment recycling.

The majority of this section of this chapter has centered around comprehensive clinical care of the patient with adult MND, emphasizing “everything that modern medicine has to offer.” The physician must consider that the patient with advanced ALS may not want all of this. Life sustaining therapy, defined as any artificial device or intervention that compensates for the failure of an organ system which would normally result

in death, is the patient’s choice, not the physician’s. The most obvious example of this would be mechanical ventilation, but this also includes artificial hydration and nutrition. Legally and ethically speaking, a mentally competent patient can refuse any prescribed treatment. It is the physician’s responsibility to make sure that the patient understands the consequences of this. The physician should always respect and foster the

#### HEALTH-CARE DIRECTIVE FOR THE INDIVIDUAL WITH AMYOTROPHIC LATERAL SCLEROSIS.

Recognizing that respiratory failure and/or inability to take in adequate nutrition is frequently the cause of death in cases of ALS, I hereby wish to state in advance my preference regarding invasive mechanical ventilation and feeding gastrostomy tube placement. It is my desire that these preferences guide the decision making of my family and my physician(s) in the event that I am unable to participate in a meaningful way in discussions regarding my health care. I understand that none of the choices made here will be put into effect without my agreement as long as I retain the capacity for decision making and the ability to communicate, in some form, those decisions.

##### I. With regard to invasive mechanical ventilation requiring endotracheal intubation, it is my preference that:

(Choose one of the following three main options):

- A. ☐ Invasive mechanical ventilation *not* be instituted under any circumstances. I understand that such a choice will almost certainly mean that my death will occur earlier than if such support is instituted. I also understand that some processes that might precipitate respiratory failure may be readily reversible and that, therefore, mechanical ventilation may not necessarily be long-term, yet I still do not wish to undergo mechanical ventilation even in such circumstances.
- B. ☐ Invasive mechanical ventilation be used only when, in the judgment of appropriate medical personnel, the acute cause of respiratory failure is believed to be likely reversible, for example, in the case of choking. If, on the other hand, respiratory failure is a result of the irreversible deterioration from ALS, I do not wish to undergo mechanical ventilation, knowing that such a choice will almost certainly mean that my death will occur earlier than if such support is instituted.  
If invasive mechanical ventilation is used and it becomes evident that long-term mechanical ventilation is required, then (choose none, one, or more of the following):
  1. ☐ I wish for mechanical ventilation to be discontinued regardless of the circumstances, knowing that this will result in my death.
  2. ☐ I wish for mechanical ventilation to be discontinued if I should be diagnosed in writing by two physicians to be in a permanent unconscious condition.
  3. ☐ I wish for mechanical ventilation to be discontinued if I become permanently unable to effectively communicate (“locked-in”).
  4. ☐ I wish for mechanical ventilation to be discontinued if I am unable to return to living at home.
  5. ☐ I wish for mechanical ventilation to be discontinued if my care results in major financial hardship or other burden on my family.
- C. ☐ Invasive mechanical ventilation should be instituted in all circumstances for respiratory failure not treatable by other measures, and long-term mechanical ventilation with tracheostomy should be continued with the following exceptions (choose none, one, or more of the following):
  1. ☐ I wish for mechanical ventilation to be discontinued if I should be diagnosed in writing by two physicians to be in a permanent unconscious condition.
  2. ☐ I wish for mechanical ventilation to be discontinued if I become permanently unable to effectively communicate (“locked-in”).
  3. ☐ I wish for mechanical ventilation to be discontinued if I am unable to return to living at home.
  4. ☐ I wish for mechanical ventilation to be discontinued if my care results in major financial hardship or other burden on my family.

##### II. With regard to nutrition provided by feeding percutaneous gastrostomy tube (PEG), it is my preference that:

(Choose one of the following two main options):

- A. ☐ I do not wish placement of a feeding gastrostomy tube at any time during the course of my illness.
- B. ☐ I wish for placement of a feeding gastrostomy tube at a time when it is necessary to provide me with nutrition and medications, as determined by my physician, regardless of my choice concerning invasive ventilation. It should be continued with the following exceptions (choose none, one, or more of the following):
  1. ☐ I wish for gastrostomy tube feeding to be discontinued regardless of the circumstances, knowing that this will result in my death.
  2. ☐ I wish for gastrostomy tube feeding to be discontinued if I should be diagnosed in writing by two physicians to be in a permanent unconscious condition.
  3. ☐ I wish for gastrostomy tube feeding to be discontinued if I become permanently unable to effectively communicate (“locked-in”).
  4. ☐ I wish for gastrostomy tube feeding to be discontinued if I am unable to return to living at home.
  5. ☐ I wish for gastrostomy tube feeding to be discontinued if my care results in major financial hardship or other burden on my family.

In all cases where I choose not to start or to discontinue mechanical ventilation or nutrition via gastrostomy tube, I instruct my physician to provide me with adequate medication to relieve anxiety and discomfort that may occur during the final course of my disease.

**FIGURE 28-8.** Example of an advanced health care directive for patients with ALS (178).

patient’s autonomy and self-direction with respect to these types of interventions (191–193). An advanced health care directive is absolutely necessary. An excellent example of this was developed by Benditt et al., and is shown in Figure 28-8 (178). This does not extend to the point of physician-assisted suicide, where the physician takes active steps to end the patient’s life (194). This is an illegal act that carries ethical concerns which are beyond the scope of this chapter. Despite this, a recent study documented that approximately 56% of ALS patients surveyed in Washington and Oregon states would consider assisted suicide (194). This stunningly high percentage of ALS patients who would consider this strongly implies that the quality of care in advanced ALS is inadequate. If the patient is requesting this, then the physician should reassess the situation, making sure that everything has been done to maximize patient comfort and quality of life.

Further, quality of life studies have identified a lack of adequate communication between physician and patient and a poor perception (both positive and negative) on the part of physician of the level of quality of life in these patients (187). It takes a great deal of time to explain all of the end-of-life issues, including the available treatment options and choices. Without this investment of time on the clinician’s part, the patient is unaware what services may be available to ease his suffering.

The most appropriate level of care for the ALS patient may change frequently and patients should be followed closely. Unfortunately, an advanced ALS patient is often told “there is nothing that can be done,” when in fact optimizing in-home care with hospice can maximize quality of life for these patients and provide for a comfortable, painless passing. Krivickas et al. documented that most ALS patients probably do not receive

enough in-home care (195). Of 98 advanced ALS patients studied, only nine received hospice home care, 24 received nonhospice home care, and seven both hospice and nonhospice home care. The remaining 58 patients received no in-home care at all. Even among those having home care assistance, non-medical ALS primary caregivers spent an average of 11 hours/day caring for patients with tracheostomy tubes; among ALS primary caregivers of patients with tracheostomy, 42% and 48% felt physically and psychologically unwell, respectively. The authors concluded that home and hospice care received by ALS patients is inadequate because it starts too late to relieve the burden placed on family caregivers. Because the focus of care in hospice is the family, however defined by the patient, this problem could be easily resolved. Hospice provides an interdisciplinary team of professionals whose mission is to support the patient and the family through their remaining days together. Support is given for physical, psychological, emotional, and spiritual needs of the family unit in the home setting, bypassing the need for laborious trips to clinics.

The National Hospice Organization does have some guidelines for entry of an ALS patient into hospice (Table 28-1), which are somewhat arduous but would allow for early entry into hospice of most ALS patients in the advanced stages of the disease (196). These guidelines require physicians to make some estimate of life expectancy, which is very difficult to do in ALS and is something for which most physicians are probably ill-prepared. Compared to terminal cancer patients, ALS has a relatively slow progression with respect to the actual dying process, which decreases the clinician’s awareness that hospice care may be appropriate. Most clinicians likely perceive that hospice is for “near terminal” patients, which is correct, except

**TABLE 28.1     Criteria for Hospice Admission in ALS**

Hospice is appropriate when there has been an overall rapid progression of ALS (a critical factor), e.g., disability has progressed significantly in the past 12 months. The patient/family desires no further aggressive treatment or cardiopulmonary resuscitation.	
In addition, at least one of the following must also apply:	
1. Increased respiratory distress	
a. Vital capacity (VC) less than 30% of predicted	
b. Significant dyspnea at rest	
c. Supplemental oxygen required at rest	
d. Patient has refused intubation, tracheostomy, and mechanical ventilation	
2. Severely impaired nutrition	
a. Tube feeding not elected or discontinued	
b. Oral intake insufficient/dysphagia	
c. Continued weight loss in spite of tube feedings	
d. Dehydration or hypovolemia	
3. Life-threatening complications	
a. Recurrent aspiration pneumonia	
b. Decubitus ulcers, multiple, stage 3–4, particularly if infected	
c. Upper urinary tract infection, e.g., pyelonephritis	
d. Sepsis	
e. Fever recurrent after antibiotics	

that ALS patients may be in that state for a prolonged period of time. During this time, hospice care could ease suffering considerably. Lack of physician knowledge of the services provided by hospice is widespread (197,198). Physicians not familiar with the care of terminal patients may not be comfortable with the aggressive use of opiates and benzodiazepines advocated by hospice clinicians for the control of symptoms in ALS. The physician may find it difficult to give carte blanche orders for effective titration of these types of medications, which will ease air hunger and anxiety in the end-stage ALS patient (Table 28-1).

Irrespective, in the final stages of the disease it is medically appropriate to involve a home hospice team. Regular home visits by hospice nurses will assure proper medication delivery, pain control, skin and bowel care, as well as providing the physician with a progress report without having to bring the patient into the clinic. They can also provide counseling to avoid panic calls to 911 by family members and unnecessary nighttime visits to the emergency room. Most patients wish to die at home, and in most cases with a supportive family and the help of hospice, this is a feasible and worthwhile goal.

An informed patient and family will welcome the comprehensive level of terminal care that hospice offers, consoled with the knowledge that dying with dignity in the serenity and security of one's own home is, in some modest but meaningful way, a measure of victory over this otherwise insufferable illness. Finally, we urge clinicians to attend memorial services since it is a healing and rewarding experience.

# Peripheral Neuropathy

## INCIDENCE, PREVALENCE, DISABILITY, AND COST

The overall incidence, prevalence, disability rates, and cost of peripheral neuropathy in the United States are unknown. There are studies, however, that hint at the scope of the problem. For diabetic peripheral neuropathy alone the estimated prevalence is more than 20 million, with an annual cost of 10.9 billion dollars (1). The annual cost of patient care and disability payments for acute idiopathic demyelinating polyneuropathy (Guillain-Barre syndrome) is approximately \$1.7 billion. An estimated 11% of patients have permanent disability (2). Of patients with vasculitic disease, approximately 60% to 70% suffer from peripheral neuropathy, and of these, 65% have mild to moderate disability, 13% moderately severe disability, and 4% severe disability (3).

## PERIPHERAL NEUROANATOMY AND NEUROPHYSIOLOGY

The peripheral nerve is vulnerable to a wide variety of insults but has a great capacity for repair and regeneration. The peripheral nerve includes the cell body, axons and dendrites, the cell membrane (neurolemma), the endoneurium, perineurium, mesoneurium, epineurium, and the Schwann cell. The specifics of these structures help understand the classification, pathophysiology, and treatment of peripheral neuropathy.

The cell body of motor nerve fibers is the anterior horn cell. The cell body of sensory nerves is located in the dorsal root ganglion. The autonomic nerve fibers in contrast to the somatic fibers have both preganglionic and postganglionic neurons, with the cell body of the postganglionic neuron lying in the periphery and extending through unmyelinated C fibers.

The axon is contained by the cell membrane, the axolemma. It contains the axoplasm which has tracts for both antegrade and retrograde flow, with the tracts maintained by electrical polarity. Axoplasmic flow occurs at 1 to 3 mm per day and is one rate-limiting aspect of nerve regeneration, although the flow can occur more rapidly in response to injury.

The axolemma of myelinated nerve fibers is enclosed by the Schwann cell, which elaborates the lipoprotein myelin. This is why lipid lowering medications are a risk factor for peripheral neuropathy (4).

The Schwann cell internode space, or node of Ranvier, is the site of membrane depolarization, saltatory conduction, and any axonal branching. In unmyelinated nerve fibers, the relationship of nerve fibers is less complex, and several fibers may be contained in the Schwann cell trough. These fibers propagate signal conduction by continuous depolarization along the axolemma (eddy depolarization).

Axon fascicles divide and fuse with others in the epineurium. Communication between fascicles occurs every 0.5 to 15 mm, more frequently in the proximal peripheral nerve. They branch between 20 and 100 times before reaching the motor endplate.

The mesoneurium supports the capillary network that supplies the nerve fibers. The mesoneurium is easily compromised and this accounts for the peripheral nerve's susceptibility to ischemia. The endoneurium contains the axon and Schwann cell in a grouped arrangement. These fascicles are in turn contained by the perineurium which maintains a positive intrafascicular pressure. This structure presents a barrier to diffusion, the blood-nerve barrier. When the perineurium is compromised, diffusion produces axonal swelling which impairs signal conduction (Table 29-1). The epineurium is a loose collection of collagen and elastin fibers that support the fascicles of a peripheral nerve. This arrangement is elaborate in the proximal nerve and becomes progressively less complicated in more distal nerve segments. The external epineurium surrounds the peripheral nerve and is largely responsible for its resistance to mechanical disruption. Its elastic properties allow a degree of deformation beyond which rupture occurs. This is why a stretched nerve is more readily injured than when at its resting length.

A number of age-related physiologic changes occur in the peripheral nervous system (5). There is a decrease in the number of anterior horn cells, a decreased capacity for neuronal sprouting, biosynthesis, transport and proliferation, and decreased Schwann cell synthesis of trophic factors. This results in slowed protective reflexes and decreased proprioception, vibratory sense, and stretch reflexes. The pain and temperature recognition thresholds increase.

## CLASSIFICATION OF PERIPHERAL NEUROPATHY

Peripheral neuropathy can be classified by etiology, pathology (including genetic error), location of the lesion, time since insult,

**TABLE 29.1** Correlation of Peripheral Nerve Anatomy and Pathology

Structure	Function	Pathologic Consequence of Impaired Function
Axon	1–3 mm axonal flow	Rate limit to healing
Schwann cell	Myelin synthesis	Susceptibility to lipid lowering medication
Mesoneurium	Capillary support	Ischemia
Perineurium	Blood-nerve barrier	Axonal swelling
Epineurium	Resistance to stretch	Vulnerability to compression injury

or clinical presentation. It may be generalized, proximal, or distal in location. Possible etiologies include trauma, metabolic disease, malnutrition, response to infection, other autoimmune disease, collagen-vascular disease, genetic error, toxin (including medication) exposure, thermal injury, or ischemia (Table 29-2).

The neuropathy can affect the axon and/or the myelin sheath. The neuropathy can result in neurapraxia, axonotmesis, or neurotmesis. The disease may be confined to a single nerve (mononeuropathy), involve multiple nerves (polyneuropathy), and be symmetric or asymmetric. The neuropathy can be acute or chronic although this may be unclear when there is an insidious onset and delayed diagnosis. Depending upon the nerve involved, the clinical presentation includes weakness, paresthesia, hypesthesia, anesthesia, or changes in autonomic function such as changes in circulation or hidrosis.

The Seddon classification of peripheral nerve pathology is clinically relevant. It can be used to predict functional outcome and suggest appropriate care (Table 29-3). There are three degrees of nerve pathology: neurapraxia, axonotmesis, and neurotmesis.

Neurapraxia is a local conduction block due to transient demyelination and rarely affects sensory or autonomic fibers. Thick myelinated nerves are most affected. Neurapraxia commonly results from compression of the peripheral nerve. These lesions heal by Schwann cell repair, and normal conduction is generally resumed in 1 to 2 months (6,7).

Axonotmesis is a more significant injury and results in Wallerian degeneration. With an axonotmetic lesion, the endoneurial tube remains intact. This lesion follows a traction

**TABLE 29.2** Classification of Peripheral Neuropathy Related to Site of Pathology

Classification	Structure Most Commonly Affected
Distribution	Proximal Distal Generalized
Pathology	Neurapraxia Axonotmesis Neurotmesis
Etiology	Traumatic Hereditary/genetic Toxic/metabolic Endocrine Nutritional Postinfectious/ autoimmune disease Vasculitic Thermal Ischemic
	One nerve Multiple nerves Myelin Axon Axon, myelin Myelin or axon, myelin Axon, myelin Axon, possibly myelin Axon Myelin Myelin Axon Axon, myelin Axon

injury or a severe nerve compression. The prognosis for regeneration is good, particularly for shorter injured or distal nerve segments. The distance of regeneration is the primary limiting factor, so recovery is less certain with proximal injury.

Neurotmesis is complete severance of the peripheral nerve trunk and is the most severe lesion. Recovery is unlikely unless neurotomy is performed (6). Healing of a neurotmetic lesion often results in the misconnection of nerve fibers and incomplete reinnervation.

## TRAUMATIC PERIPHERAL NERVE INJURY AND SUBSEQUENT DEGENERATION AND REGENERATION

Traumatic peripheral nerve injury can result from compression, crush injury, laceration, stretch/traction, ischemia, thermal injury, or high-velocity trauma (Table 29-4). Further injury of the peripheral nerve may result from associated infection, scar tissue formation, fracture callus, or vasculopathy.

**TABLE 29.3** Correlations of the Seddon Classification of Peripheral Nerve Pathology

Class	Cause	Consequence	Usual Site Affected	Prognosis
Neurapraxia	Compression	Conduction block	Thick myelinated motor nerves	Healing in 1–2 months
Axonotmesis	Traction Severe compression	Wallerian degeneration	Myelinated motor and sensory nerves	Good for healing if short or distal motor or sensory segments are affected
Neurotmesis	Trauma Transection	Complete disruption of nerve continuity	Any	Poor, even with surgery

**TABLE 29.4** Traumatic Causes of Peripheral Neuropathy

Compression  
Crush injury  
Laceration  
Stretch/traction  
Thermal injury  
High-velocity trauma

The most common mechanism of traumatic nerve injury is transection due to blunt or penetrating trauma. In such instances, there may be a delay in diagnosis due to adjacent tissue injury.

Fracture and fracture/dislocation carry a high risk of associated nerve damage. Nerve injury after shoulder dislocation occurs in 48% of cases. The incidence of radial nerve damage following humeral fracture is 11% (8). Ulnar neurapraxia is the most commonly identified nerve lesion associated with fracture dislocation at the elbow. Dislocation of the hip is associated with a nerve injury rate of 3% and the rate associated with knee dislocation is 18% (8).

Iatrogenic injury can also occur. Plating of forearm fractures results in a reported nerve injury in 1% to 10% of cases. Damage has also been reported during elbow and shoulder arthroscopy (9,10).

Compression injury of a peripheral nerve generally results in focal demyelination. This causes a conduction block. Recovery depends upon remyelination. With all peripheral nerve lesions that leave the axon intact, there is axonal transport of tumor necrosis factor alpha (TNF  $\alpha$ ) to the lesion and a concomitant reorganization of peripheral nerve TNF receptors (11).

A crush injury provokes segmental demyelination but the Schwann cell tube is commonly preserved and recovery can occur. A laceration injury due to blunt or penetrating trauma produces a well-localized lesion, usually millimeters in size. A stretch of the peripheral nerve beyond 10% to 20% of its resting length increases the risk of axonotmesis (9). This is the common mechanism of injury during joint dislocations. Stretch alone may provoke a mild conduction block which recovers in hours. A more severe stretch will interrupt axons and connective tissue, cause hemorrhage and might require surgical repair.

Cold injury can cause necrosis of all tissues. Large myelinated fibers are most susceptible to cold injury. Damage to the blood-nerve barrier results in endoneurial edema and increased intraneurial pressure, with a resulting focal conduction block. If the pathology is progressive, axonal transport ceases and the axon degenerates within a few days.

Peripheral nerves vary in their vulnerability to compressive, thermal, or traumatic injury. Fiber-type composition, size of the nerve, number of nerve fascicles, amount of soft-tissue protective cushioning, course of the nerve (on bone, through

fascia or muscle), and tethering all affect the nerves' ability to sustain and spontaneously recover from injury. For example, the peroneal division of the sciatic nerve is tethered at the fibular neck and at the sciatic notch and is more vulnerable than the tibial division, which is tethered at the sciatic notch alone. Scar formation, heterotopic ossification, and fracture callus can tether the peripheral nerve.

## Degeneration

Primary, or retrograde, degeneration is a consequence of trauma and is less common than secondary (Wallerian) degeneration. The degenerative process proceeds from the site of injury to the next proximal node of Ranvier (6).

Secondary or Wallerian degeneration is antegrade, progressing distally from the point of injury (7). Wallerian degeneration begins on the second or third day after injury, with retraction of myelin. Nerve fragmentation on day 2 to 3 precedes neurofibrillar degeneration. The nerve body swells. Neuron edema continues for 10 to 20 days. These changes are more pronounced and longer lasting with proximal nerve lesions. The Schwann cells at the site of injury activate and, by the end of the first week after injury, participate in the removal of myelin debris.

## Regeneration

Axonal regeneration and remyelination progress in a sequence that follows degeneration of the injured nerve segment beginning with the activation of Schwann cells in the empty endoneurial tube. Axonal sprouts appear and progress down the endoneurial tube. These regenerating axons are guided along the perineurium by neutropins. They are directed toward the largest surviving distal fascicles (9).

The peripheral nerve can form a neuroma during the repair process. This may be a nerve stump neuroma (neuroma in continuity) which is usually located lateral to the nerve trunk. It forms as axonal/fascicular continuity is reestablished. A laterally located neuroma indicates partial neurotmesis with preserved ability to conduct signals. When the neuroma is imbedded in scar tissue, the prognosis for recovery is worse. A fusiform-shaped neuroma is likely to be in continuity, while a bulbous or dumbbell-shaped neuroma is indicative of widespread neurotmesis. This should be treated by excision and neuroorrhaphy. (Surgery following trauma is discussed in the treatment section of this chapter.) Similarly, if more than 50% of the nerve trunk is involved, function will be impaired and the neuroma should be resected (6).

Initially, unmyelinated axonal sprouts unite with the distal peripheral nerve remnant, then remyelination begins. Both sheath and axon increase in diameter. If the gap in continuity is greater than 2 mm, reconnection is much less likely. In such instances, the immature neurite (sprout) dies back or forms a neuroma.

Later, a shrinking area of sensory loss with an enlarging area of partial sensation occurs as anastomotic branches with other nerves form (12). Involvement of autonomic fibers causes anhidrosis and impaired pilomotor and vasomotor activity.

If the skin wrinkles on immersion in water, or if sweating is present, the peripheral nerve damage is incomplete.

As recovery progresses, there is a return of pain and temperature sensation, a return of sudomotor function, and later a return of light touch, vibratory sensation, and stereognosis. Perhaps the best predictor of outcome is two-point discrimination which positively correlates with a return of function (6).

A nerve percussion sign is indicative of demyelination/remyelination. When the nerve percussion sign progresses from a proximal location in the nerve to more distal segments, healing is taking place by regenerating sprouts and incomplete myelination (13).

## NONTRAUMATIC PERIPHERAL NEUROPATHIES

The peripheral nerve axon is particularly vulnerable to toxic, metabolic, endocrine, and genetic insults. The myelin sheath is most commonly affected by autoimmune, nutritional, or genetic disorders and toxic or metabolic disease. In the United States, diabetes and alcohol abuse are the most frequent agents of peripheral nerve injury. Fifteen to twenty percent of nontraumatic peripheral nerve injuries are idiopathic (14).

Injury results in an increase in the neuropeptides galanin and pituitary adenylate cyclase-activating peptide with a net neurite outgrowth that can result in excessive branching during repair (15).

## HEREDITARY PERIPHERAL NEUROPATHIES

The hereditary peripheral neuropathies include the hereditary sensory motor neuropathies (HSMNs) types I and II (Charcot-Marie-Tooth [CMT] disease), type III (Dejerine-Sottas disease), type IV (Refsum's disease), and HSMN types V–VII (Table 29-5). Other inherited peripheral neuropathies include Friedreich's ataxia, pressure-sensitive hereditary

neuropathy, and various diseases that include altered structure or function of the peripheral nerve such as acute intermittent porphyria, Roussy-Levy syndrome, Riley-Day syndrome, Fabry disease, and Pelizaeus-Merzbacher disease. These neuropathies demonstrate segmental demyelination and remyelination of the peripheral nerve, resulting in a slowing of signal conduction (16). Large myelinated motor fibers are the most severely affected (17). The distribution of weakness and atrophy includes the peroneal and distal leg muscles, and the peak strength loss is between 60% and 80% (18). Sensory loss and areflexia are notable. Atrophy and weakness in the upper extremities are less prominent.

Inheritance of a HSMN is usually autosomal dominant with variable penetration. Autosomal recessive and X-linked diseases occur less frequently and generally have a poorer prognosis.

The mutations in HSMN affect the genes that encode myelin proteins. Several abnormalities have been identified. These include duplication of chromosome 17p11.2, resulting in abnormalities of peripheral myelin protein 22 (19,20). The mutation produces abnormal endoplasmic proteins that lead to Schwann cell apoptosis (21). The specifics of myelin gene mutation determine disease severity. Deletion of myelin protein zero results in the most severe disease. Deletion of the 17p11.2 chromosome results in a hereditary neuropathy with susceptibility to pressure palsies. Point mutation of the PO gene and defects of the connexin 32 gene (which encodes a gap junction protein) occur in X-linked forms of HSMN (22). In 30% of CMT type II disease, there is a defect in mitofusin 2 genes with a decoupling of mitochondria in the axon, leading to decreased oxidative phosphorylation (23).

CMT type I can also be defined by the genetic error. Type Ia CMT disease results from a defect in chromosome 17. In type Ib CMT disease, the defect is located in chromosome 1.

The prevalence of the most common neuropathy, HSMN type I and II CMT disease, ranges from 1 per 50,000 to 1 per 250,000 (24–27). The clinical manifestations are variable. The slowly progressive weakness is symmetric and more pronounced in distal musculature. In type I disease, the myelin is affected and onset is within the first decade of life. In type II disease, the axon is most affected and onset is usually within the second decade. For both type I and type II, the onset is often insidious and the patient asymptomatic until much later. The distribution of sensory deficit parallels that of the motor deficit. Loss of balance and tripping due to foot drop are often noted, as are deformities such as equinovarus, calcaneovalgus, and pes cavus. Pain is uncommon.

CMT type II inheritance is more heterogeneous than in type I, with wider phenotypic variation. The resulting disability ranges from very mild to severe. Type II disease is characterized by less hypertrophic change in myelin and more neuronal or axonal involvement than is seen in CMT type I (19,20,28–31).

HSMN type III, Dejerine-Sottas disease, is another inherited hypertrophic peripheral neuropathy with prominent demyelination and remyelination. Neurapraxia is typical of this disease (29). Patients present with delay in motor

**TABLE 29.5 Hereditary Sensory Motor Neuropathies**

Type	Name
I	Charcot-Marie-Tooth (CMT) disease
II	CMT
III	Dejerine-Sottas disease
IV	Refsum's disease
V	With spastic paraplegia
VI	With optic atrophy
VII	
Other inherited diseases associated with peripheral neuropathy	Friedreich's ataxia, pressure-sensitive hereditary neuropathy, porphyria, Roussy-Levy syndrome, Riley-Day syndrome, Fabry disease, Pelizaeus-Merzbacher disease

development, difficulty running and jumping, and weakness affecting the arms as well as legs.

Refsum's disease (HSMN type IV) is characterized by altered mitochondria within the Schwann cell, and a similar abnormality is likely in other HSMN types (24). HSMN type V is associated with prominent spinocerebellar degeneration, type VI with optic atrophy, and type VII occurs with retinitis pigmentosa.

In the HSMNs, ambulation is frequently impaired and falls are common. Rehabilitation interventions focus on maintaining a safe and effective gait. Bracing, particularly ankle-foot orthoses (AFOs), usually provide adequate support. If contractures require surgical release, postoperative bracing or splinting is essential. Attention to footwear is important, particularly as equinus/cavus deformities typically occur. A comfortable, protective shoe with adequate depth and reinforced medial counter helps avoid pain, skin breakdown, and progressive deformity. Exercise is most effective for strengthening the proximal muscles of the lower extremities (32).

## IMMUNE-MEDIATED PERIPHERAL NEUROPATHIES

In the peripheral nerve, immune-mediated demyelinating processes attacks myelin and produces vasculitis and ischemia (33). The inflammatory mechanism is both cellular and humoral (34). TNF  $\alpha$  modulates the immune response, particularly in T-cell-mediated tissue injury.

The acute demyelination characteristic of AIDP results from postinfection antibodies that recognize glycolipids and gangliosides GM1, GD12, and GD16. Lymphocytic infiltration of the spinal roots and peripheral nerves aids macrophages in myelin stripping.

Acute inflammatory demyelinating polyneuropathy (AIDP, Guillain-Barre syndrome) is most typically a postinfection demyelination of the peripheral nerve with both perineurial and axonal damage. There is a breakdown of the blood-nerve barrier and segmental, macrophage-mediated damage to the myelin sheath. Inflammation and demyelination result in varying degrees of axonal degeneration, and neurapraxia is prominent.

Sixty-seven percent of patients with AIDP have a history of preceding viral infection, immunization, surgery, or a disease affecting the immune system. AIDP presents with acute onset of weakness, hypotonia, and areflexia (35). The weakness is progressive and involves the extremities. Bulbar and facial muscles can be affected. Autonomic dysfunction and sensory symptoms are usually mild (34). Respiratory failure occurs in up to 30% of cases within 1 to 2 weeks after disease onset (36). Recovery generally takes 3 to 18 months. Residual weakness is common and usually mild.

The Miller Fisher syndrome is a relatively benign variant, occurring in about 5% of AIDP cases. It is characterized by ophthalmoplegia, areflexia, and ataxia (34). Antibodies to GQ1b are common.

Acute motor axonal neuropathy (AMAN) is an axonal variant that follows *C. jejuni* infection. Wallerian degeneration occurs. The clinical presentation is similar to that of AIDP but myelin is not affected. The antibody mediators include GM1, GD1a, and GD16 (34).

Acute motor sensory axonal neuropathy (AMSAN) is another clinical syndrome characterized by axonopathy. There is also a sensory variant of AIDP and, most rare, an acute pandysautonomia.

The medical management of AIDP includes the administration of high-dose immunoglobulins, plasmapheresis, or plasma exchange (37–39). Treatment reduces the duration of paralysis and intubation, particularly in the most severe cases (39). Cerebrospinal fluid filtration of antibody complexes can be useful. Corticosteroid therapy has no proven efficacy.

The rehabilitation management of AIDP focuses on the prevention of contractures, skin breakdown, pneumonia, and depression. During the acute phase, communication devices, a trapeze, pressure relief bed surfaces, and bed rails are helpful. Because AIDP presents with evolving weakness, strengthening, bracing, adaptive equipment, and vocational retraining are not appropriate until the clinical findings have stabilized. Retraining for activities of daily living (ADLs), wheelchair and ambulation training, and bracing may be necessary if there is significant residual impairment and disability.

Chronic inflammatory demyelinating polyneuropathy (CIDP) is a T-cell-mediated autoimmune peripheral neuropathy. It involves motor and sensory fibers. Disability results from weakness of both proximal and distal muscles (40). Cramps and fasciculations are common in the upper extremities (41).

The differential diagnosis of CIDP includes HSMN and amyotrophic lateral sclerosis. Histologic changes characteristic of CIDP include mononuclear cell infiltrates, prominent endoneurial edema, and wide interfascicle variability. CIDP can be associated with malignancy, particularly melanoma, due to shared immunoreactivity with common surface antigens present in both the myelin and the tumor (42).

The medical management of CIDP includes high-dose intravenous immunoglobulins, immunosuppressive drugs, or immune adsorption (43). Treatment with steroids is probably not effective (44). There is evidence that CIDP responds well to stem cell therapy (45).

Other immune neuropathies include multifocal acquired demyelinating sensory and motor neuropathy (Lewis Sumner syndrome, MADSAM), distal acquired demyelinating symmetric neuropathy, and multifocal motor neuropathy (Table 29-6) (46–48). Other forms of the disease are the subacute inflammatory demyelinating polyneuropathy (SIDP) and monoclonal gammopathy of undetermined significance (MGUS) (49,50).

Critical illness polyneuropathy (CIP) can present as failure to wean from mechanical ventilation (50,51). In septic multisystem organ failure, the systemic inflammatory response syndrome or high fever leads to a polyneuropathy of mixed or

**TABLE 29.6 Immune-Mediated Peripheral Neuropathies**

Other: rheumatoid arthritis, systemic lupus erythematosus, Wegener's granulomatosis, celiac disease

motor nerves (50,52–57). High-dose intravenous steroids have also been implicated in the production of CIP. Electrodiagnostic studies are key in the diagnosis and monitoring of CIP since the clinical findings of CIP can be obscured by the primary medical condition, steroids, neuromuscular blocking agents, or concomitant compression neuropathies. The differential diagnosis includes critical illness-associated transient neuromuscular blockage, thick-filament myopathy, and necrotizing myopathy (52).

CIP may result from cytokine and free radical release during sepsis which impairs peripheral nerve microcirculation (58). Noninflammatory axonal degeneration and resulting neurogenic muscle atrophy occur in distal motor fibers, although there is often striking weakness of the proximal muscles and diaphragm (59). Sensory fibers are minimally affected (56,59).

CIP produces moderate to severe weakness in all limb, facial, and paraspinal muscles, and atrophy is prominent. Peroneal nerve residual weakness is most common. Loss of deep tendon reflexes is inconsistent. Serial serum creatine kinase levels and serial electrodiagnostic testing are helpful in monitoring the disease course.

Recovery time from CIP ranges from 3 weeks to 6 months (59). The prognosis is good if the patient survives the precipitating critical illness.

Rehabilitation efforts for CIP patients focus on preventing decubitus ulceration, contractures, and compression neuropathies. Strengthening exercise, mobility and ADL retraining, as well as appropriate orthotics and adaptive equipment, should be provided at appropriate stages of recovery.

Other diseases that alter peripheral nerve function include benign monoclonal gammopathy (IgG, IgA, or IgM), chronic liver or pulmonary disease, cryoglobulinemia, giant cell arteritis, gout, and necrotizing angiopathy (60). Paraneoplastic or paraproteinemic peripheral neuropathies occur in association with various malignancies such as lymphoma; multiple myeloma; bronchogenic carcinoma; ovarian, testicular, penile, gastric, oral cavity, and meningeal cancers; oat cell carcinoma; and osteosclerotic myeloma.

## TOXIC, NUTRITIONAL, METABOLIC, AND ENDOCRINE PERIPHERAL NEUROPATHIES

Toxic peripheral neuropathy results from exposure to a variety of organic and inorganic toxins, medications, and heavy metals (Table 29-7). Many toxic peripheral neuropathies resolve with appropriate treatment. Many commonly prescribed therapeutic drugs, environmental pollutants, industrial solvents, and other workplace chemicals can be neurotoxic. Peripheral neuropathy is one of the most common responses of the peripheral nerve to chemical attack (61). Most toxins produce distal axonal degeneration in the longer peripheral nerves. There are several toxic agents that damage the neuron directly or induce primary demyelination (61). Therapeutic drugs that can cause neuropathy include  $\alpha$  interferon, amiodarone, amitriptyline, chloramphenicol, chloroquine, cimetidine, colchicine, corticosteroids, cisplatin, dapsone, didanosine, diphenylhydantoin, disulfiram, ethambutol, hydralazine, isoniazid, lithium, metronidazole, nitrofurantoin, nitrous oxide, paclitaxel, phenytoin, pyridoxine, sodium cyanate, suramin, tetanus toxoid, thalidomide, and vincristine (14). The pathogenesis differs between therapeutic agents. Cisplatin and suramin, for example, result in apoptosis of neurons in the dorsal root ganglion.

**TABLE 29.7 Toxic, Nutritional, Metabolic and Endocrine Peripheral Neuropathies**

Etiology	Disease or Agent	Cause	Presentation
Toxic	Organic Inorganic Medication	Distal axon of longer peripheral nerves	Stocking-glove sensory loss followed by distal motor weakness
Nutritional	B vitamins deficiency or toxicity	Axon	Pain
Metabolic	Renal failure Porphyria	Axon	
Endocrine	Diabetes Thyroid	Axon Myelin	Variable

Nucleoside reverse transcriptase inhibitors (62), deplete peripheral nerve mitochondrial DNA, and DNA polymerase activity (63). They may respond to treatment with acetyl-L-carnitine for the treatment of pain and decreased sensory fiber function (62).

Neurotoxic organic compounds include acrylamide, carbon disulfide, dichlorophenoxyacetic acid, ethyl alcohol, ethylene oxide, methylbutyl ketone, and triorthocresyl phosphate. Heavy metals that may be neurotoxic include antimony, arsenic, gold, lead, mercury, and thallium.

Toxic peripheral neuropathies typically present with a glove and stocking distribution of sensory loss (64). This is followed by weakness in the same distribution. The presentation may be protracted and insidious as is common with nutritional or endocrine etiologies. Recovery can take several months to years following appropriate treatment (61).

Nutritional deficiencies (B1, thiamine [beriberi or pellagra], riboflavin [B2], pyridoxine [B6], B12 [pernicious anemia], and protein or calorie deficiency) and endocrine disease (diabetes, thyroid, or parathyroid) exposure can also damage the peripheral nerve axon.

DIABETIC PERIPHERAL NEUROPATHY

Diabetic neuropathy affects between 5% and 50% of diabetics in the United States (65). The incidence of peripheral neuropathy increases with age, duration of diabetes and mean serum glucose (65,66), smoking, HTN, height, and hyperlipidemia. Average annual incidence is 2% of diabetics and 0.56% have severe symptoms and deficits. The prevalence among people with diabetes for longer than 25 years is 50%. Diabetic peripheral neuropathy can affect motor, sensory, cranial, and autonomic nerves in the nerve root, plexus, or peripheral nerve. It will present as a mononeuropathy, mononeuritis multiplex, a distal symmetric or proximal symmetric neuropathy, autonomic neuropathy, polyradiculopathy/amyotrophy, and/or a generalized painful peripheral neuropathy (Table 29-8) (67).

In diabetic neuropathy, there is endoneurial and epineurial lymphocyte infiltration that disrupts signal conduction (68). The microvascular ischemia affecting the peripheral

nerve is due to impaired endogenous fibrinolysis. The vascular changes are mediated by the polyol pathway—sorbitol and aldose reductase deposit glucose in tissues that are insulin independent (retina, kidney, nerve). Accumulation of sorbitol produces osmotic stress on the cell membrane while at the same time decreasing nitric oxide and vasodilation. The net result is microvascular disease due to vasoconstriction, thickening of the capillary basement membrane, endothelial hyperplasia, and a resulting decrease in oxygen tension and hypoxia.

There is an increasing refractory period before overt slowing of nerve conduction velocity is seen (69). Laser Doppler flowmetry can demonstrate sympathetic involvement when testing reveals an abnormal vascular response (70).

Strict control of serum glucose will retard the development or progression of diabetic neuropathy (71,72). There is also increasing evidence that antioxidant therapy, aldose reductase inhibitors,  $\alpha$ -lipoic acid, and  $\gamma$ -linolenic acid may play a role in preventing, halting, or improving diabetic neuropathy (73,74). Brain-derived nerve growth factor (NGF), recombinant NGF, neurotrophin 3, granulocyte stimulating factor, and other peptides have also been used to treat diabetic neuropathy with limited success (75–77). In animal models of diabetic peripheral neuropathy, an increase in nerve conduction velocity was seen with implantation of hematopoietic mononuclear cells from peripheral blood or marrow (78). Similar results were obtained with small neurotrophic nonneural peptides (“dual-action peptides”) (79).

The most common complaint is of tingling or burning paresthesia in the feet, ankles, and calves. Due to distal weakness, postural control shifts from the ankle to hip, increasing the work of remaining upright. Autonomic neuropathy causes arteriovenous shunting and tissue hypoxia in the feet as well as in other organ systems. Pain, skin breakdown, and amputation are other complications of diabetic peripheral neuropathy.

It is essential to thoroughly educate the patient regarding footwear, foot care, and the need to maintain adequate glycemic control. Shoes should be wide, deep and have an open throat design (Blucher last is preferable over Balmoral last). There should be adequate medial counter and arch support. Shoe orthotics can improve pain and ambulation when foot deformity or dynamic instability results from intrinsic muscle weakness. Pain can be managed with analgesics, tricyclic antidepressants, tizanidine, antihistamines, and anticonvulsants (including pregabalin and gabapentin). Other agents with some efficacy include topical capsaicin, counterirritants, topical lidocaine, and transcutaneous nerve stimulation (80).

INFECTIOUS PERIPHERAL NEUROPATHY

Viral Infection

The peripheral nerve can be damaged by infection as well as by the response to infection. The most common viral diseases that affect the peripheral nerve are human immunodeficiency virus (HIV), cytomegalovirus, Epstein-Barr virus, herpes zoster,

TABLE 29.8 Classification of Diabetic Peripheral Neuropathy

		Focal limb
Superimposed CIDP		

Hepatitis C, poliomyelitis, parvovirus, and rabies. West Nile viral infection can produce lesions in the anterior horn cell and motor axon similar to acute poliomyelitis (81). Leprosy remains the most common peripheral neuropathy worldwide.

As many as 50% of patients with chronic HIV have some form of peripheral neuropathy, commonly undiagnosed (82). HIV-related peripheral neuropathies include AIDP, CIDP, mononeuritis multiplex, lumbar polyradiculopathy, and lymphomatous neuropathy (83,84). The degree of neurological impairment parallels the plasma HIV1 RNA level (84).

### Bacterial Infection

Lyme disease, leprosy, and diphtheria can also produce a peripheral neuropathy.

Infection with *Borrelia* (Lyme disease) can produce several patterns of peripheral neuropathy. The most common pattern occurs late in the disease course. It is a large fiber axonopathy which causes a sensory polyneuropathy (85). Compromise of the endoneurial vascular supply can produce a mononeuritis multiplex (86).

Treatment of the infectious neuropathies addresses the concurrent infection. Appropriate antibiotic or antiviral agents should be prescribed. Hyperbaric O<sub>2</sub> can salvage peripheral nerve fibers from infection as well as ischemic, toxic, or antibody-mediated degeneration (87). Hyperbaric O<sub>2</sub> can improve symptoms of neuropathy in HIV patients (88). In these patients, recombinant NGF also appears to be useful (89).

Rehabilitation management goals include increasing strength or compensating for weakness with bracing or adaptive equipment in order to restore or maintain independent function. Exercise may focus on stretching, strengthening, or improving endurance. Splinting, bracing, and/or adaptive equipment are usual components of the rehabilitation prescription.

## NERVE ENTRAPMENT/COMPRESSION SYNDROMES

Nerve entrapment/compression syndromes are common and may involve almost any peripheral nerve (Table 29-9). Long peripheral nerves such as the median, ulnar, radial, peroneal, and tibial nerves are most vulnerable, usually in their more distal segments. Compression can be acute or chronic and result from external compression, swelling of the nerve or compression of vascular supply, and ischemia. Pressure and rigidity in fascial compartments can result in neurapraxia due to segmental demyelination. There are changes in the intraneurial microcirculation, impairment of axonal transport and changes in vascular permeability, all of which contribute to edema formation and block conduction (90). Risk factors include a rise of pressure within a contained site (e.g., fluid retention before menses or tendon thickening/edema from overuse), rigid containment (carpal tunnel borders), a pathologic increase in nerve caliber (edema or hypertrophic remyelination), stretching or tethering the nerve with a related increase in resting tension, or the presence of anomalous muscle or bone in a common confined space. The best diagnostic tool to confirm and stage an entrapment neuropathy is the electrodiagnostic evaluation.

Conservative treatment options for entrapment/compression syndromes relieve pressure and nerve compression. Strategies include splinting to restrict motion of a joint and reduce the intermittent increase in pressure on the nerve. Treatment should be prescribed for any underlying condition that leads to fluid retention, or for any abnormality that produces thickening of tissue such as in myxedema, gout, or acromegaly. Medications, including local injection of steroids, can reduce inflammation, edema, and pain. Other therapeutic modalities utilized include massage and tendon mobilization. Splinting can improve hand position function as well

**TABLE 29.9** Compression/Entrapment Peripheral Neuropathy

Nerve	Sites of Entrapment
Cervical/thoracic neurovascular bundle	Scalene muscles
Thoracic outlet syndrome	Accessory rib
	Pancoast tumor
Median nerve	Flexor retinaculum (carpal tunnel)
Ulnar nerve	Elbow (ulnar sulcus, heads of the flexor carpi ulnaris, cubital tunnel)
	Guyon's canal
	Hypothenar eminence
Radial nerve	Circumflex portion at midhumerus
	Proximal to supinator margin
	Arcade of Frohse
Lateral femoral cutaneous nerve	Along pelvis
	Exiting pelvis
	Iliac crest and anterior superior iliac spine
Peroneal nerve	Fibular head
Tibial nerve	Lancinate ligament (tarsal tunnel)

limit motion that may be contributing to a stretch injury of the nerve. Surgical release is indicated when nonoperative management fails, when acute compression requires immediate relief of pressure to preserve viability of the nerve, or in the presence of an anomaly or foreign object causing nerve compression.

### Thoracic Outlet Syndrome

The neurologic (versus vascular) thoracic outlet syndrome (TOS) produces symptoms in median and/or ulnar nerve distributions. Examination findings suggest lower trunk involvement, specifically intrinsic hand muscle weakness. Sensory impairment can be seen in a C8 to T1 distribution.

Etiologies most commonly involve compression between the scalene muscles heads, an accessory rib, or compression by a Pancoast tumor. The rehabilitation prescription emphasizes shoulder and neck range of motion, posture, and strengthening of the shoulder girdle. If conservative measures fail, surgical intervention focuses on correction of the anatomic cause of the syndrome.

### Median Nerve

The most common entrapment syndrome is carpal tunnel syndrome (91,92). The usual presenting complaint is waking with hand or finger pain and paresthesias. Another common complaint is clumsiness of the hand and dropping objects. In approximately 50% of patients there is no clear etiology. More than 50% of patients eventually have bilateral complaints (93).

Carpal tunnel etiologies include repetitive trauma, pregnancy, rheumatoid arthritis, anomalies of muscle or tendon, gout, myxedema, amyloid deposition, trauma with fracture, and scleroderma.

On examination, there is diminished touch, two-point discrimination, and weakness in a distal median nerve distribution. There is sensory sparing of the thenar eminence (median palmar cutaneous nerve) and of the skin in the ulnar and superficial radial nerve distributions.

Examination of the median innervated thenar muscles can reveal atrophy. Abductor pollicis brevis muscle weakness can be present, but there is no weakness of the median-innervated forearm muscles.

Provocative tests can produce or worsen paresthesias in the median digital nerve distributions. The Tinel's, or nerve percussion, sign (tapping over the median nerve at the flexor retinaculum) and eliciting distal paresthesias indicate demyelination/remyelination. Phalen's maneuver (the wrist in complete flexion) or reverse Phalen's maneuver (maximum dorsiflexion) supports the diagnosis of carpal tunnel syndrome. Direct compression over the distal edge of the carpal tunnel can also provoke paresthesias.

The treatment of carpal tunnel syndrome includes use of a volar wrist splint to limit wrist motion and place the wrist in a neutral position. The more time the splint is used daily the greater the reduction in symptoms (94). Local steroid injection into the carpal tunnel, or medications for neuropathic pain, can be helpful. Modalities, massage, range-of-motion exercises,

stretch of the transverse carpal ligament, and tendon-gliding exercises are useful. Ergonomic modifications place the wrist in a neutral position and reduce carpal tunnel symptoms related to work.

When conservative treatment fails, surgery is considered. A good outcome requires complete section of the transverse carpal ligament. The approach may be either open or endoscopic. The open surgery is technically less demanding and has a lower risk of complications (95). The endoscopic method results in earlier return to work and activities of daily living. There is a higher incidence of recurrence after endoscopic carpal tunnel release (95).

Acute carpal tunnel syndrome due to wrist fractures or dislocation with injury to the median nerve is another indication for surgical release.

### Impact on Vocation

Entrapment neuropathies and compression neuropathies can have a profound impact on vocation. Numbness, tingling, and weakness can lead to a deterioration in the quality and productivity of work (96).

Carpal tunnel syndrome is the most frequent entrapment/compression neuropathy that affects work. Several factors are associated with a poor prognosis for return to work, such as strenuous work activity, an occupational history of repetitive hand movements, involvement in a worker's compensation case, and use of vibrating tools. The etiology of compression is generally flexor tendon inflammatory swelling due to repetitive strain. Treatment includes control of inflammation, ergonomic assessment, and modification of the workstation and tools used.

### Ulnar Nerve

Ulnar nerve entrapment or compression can occur at several points along the nerve course. Most common are the elbow (within the ulnar sulcus or more distally between the heads of the flexor carpi ulnaris) in the cubital tunnel and at the wrist (Guyon's tunnel, between the hook of the hamate and pisiform). Compression can also occur most distally within the hypothenar eminence (generally due to repetitive strain injury). The ulnar nerve can also be compressed between the elbow and wrist when there is anomalous exit of the nerve through the flexor carpi ulnaris. Examination exposes weakness of the ulnar forearm muscles, flexor digitorum profundus (ulnar), and the flexor carpi ulnaris, depending upon the level of compression. Weakness may be limited to the ulnar intrinsic hand muscles. Sensory deficits in the ulnar branch at the hand dorsum help to differentiate between proximal compression and compression within Guyon's tunnel.

### Radial Nerve

Radial nerve compression can occur at several sites along the course of the nerve. Exam findings correlate well with the level of compression. Weakness can occur in the elbow, wrist, or finger extension. Sensory loss can be noted in the posterior arm, forearm, or hand.

Weakness of the triceps is compatible with entrapment proximal to the circumflex portion of the nerve at the mid-humeral level. Brachioradialis weakness with normal triceps strength suggests a lesion distal to the circumflex portion of the nerve. Sparing of the extensor carpi radialis is noted in entrapment proximal to the supinator margin, at the arcade of Frohse. A posterior interosseous nerve compression involves the flexor carpi ulnaris and long finger extensors without sensory involvement. A superficial radial nerve lesion produces sensory findings without weakness.

Splinting may be helpful if recovery is anticipated. Dynamic orthoses can provide wrist and finger extension if necessary, although power grasp remains compromised. Surgical release is most commonly needed when the nerve is compressed at the arcade of Frohse.

### **Lateral Femoral Cutaneous Nerve**

#### **Meralgia Paresthetica (Bernhardt-Roth Syndrome)**

This is most commonly seen in middle age. There is a gender predisposition for males. Meralgia paresthetica presents as pain or irritation over the anterior or anterolateral thigh and results from injury, compression, or disease of the lateral femoral cutaneous nerve (LFCN). Entrapment can occur near the spinal column, within the abdominal cavity as the nerve courses along the pelvis and as it exits the pelvis (the most common site). It can also be caused by superficial compression near the iliac crest and Anterior superior iliac spine. Tight clothing, trauma (such as acute compression by a seatbelt during rapid deceleration), gynecologic etiologies (related to menstrual cycle, endometriosis, or fetal compression during the second and third trimesters), and obesity are not uncommon causes. Less likely but possible etiologies include pelvic fracture, pelvic osteotomy, hysterectomy, tumor, hemorrhage, and abscess. On examination, hip extension may increase, and flexion may decrease, angulation and tension of the LFCN and symptoms.

Up to 20% percent of the time, meralgia paresthetica is bilateral. Treatment includes correction of leg length discrepancy to minimize hip hyperextension on the affected side and corticosteroid injection at the inguinal level (97).

### **Peroneal Nerve**

The most common site of peroneal nerve compression is behind the fibular head. Ankle dorsiflexor, foot evor and toe extensor weakness, and hypesthesia in the leg and foot, are typical findings. Sensory loss occurs in both the deep and superficial peroneal nerve distributions. The common peroneal nerve sensory territory at the proximal half of the lateral leg is spared, as are muscles innervated proximal to the knee. Treatment may include prescription of an appropriate ankle-foot orthosis, range-of-motion exercises, and strengthening exercises.

### **Tibial Nerve**

The most common entrapment of the tibial nerve occurs at the tarsal tunnel. There is pain and/or paresthesia of the

medial heel and plantar foot. The medial arch is variably involved depending upon the saphenous nerve sensory territory. There may be a history of foot injury or deformity such as pes planus. A nerve percussion sign may be present at the tarsal tunnel.

Foot orthoses can compensate for weakness and may help to relieve associated pain. Surgical release of the lacinate ligament is an option when nonoperative treatment does not provide symptomatic relief.

## **TUMORS OF THE PERIPHERAL NERVE SHEATH**

The nerve sheath tumors that can undergo malignant transformation include schwannomas and neurofibromas. In neurofibromatosis type 1 (NF1 gene mutation), there is loss of the tumor suppressor gene on chromosome 22, decreasing neurofibromin production. Pain is present 30% of the time. Malignant transformation is most common with NF type 1 (10%) and should be suspected when there is rapid enlargement of the nerve tumor (98,99).

## **DIAGNOSIS OF PERIPHERAL NEUROPATHY**

The diagnosis of peripheral nerve injury must be accurate in order to select the most appropriate intervention or repair (Table 29-10). It is based on the clinical examination and the electrodiagnostic evaluation.

### **Clinical Findings**

Manual muscle testing will reveal weakness in a peripheral nerve distribution. Muscle atrophy can reach 50% to 70% of the muscle bulk after about 2 months. The sensory exam may identify an impaired sense of sharp or light touch and two-point discrimination. Later, a shrinking area of sensory loss with an enlarging area of partial sensation indicates that anastomotic branches with other nerves are forming (12).

Involvement of autonomic fibers is evidenced by a loss of sweating and impaired pilomotor and vasomotor action. If the skin wrinkles on immersion in water, or if sweating is present, the peripheral nerve damage is incomplete.

A nerve percussion sign is indicative of demyelination/remyelination. When the nerve percussion sign progresses from being positive in the proximal nerve to being positive in sequentially more distal nerve segments, healing takes place. This distally advancing Tinel's sign occurs as the nerve recovers from a Sunderland II or III lesion (13).

The best diagnostic tool to characterize/confirm the presence of peripheral neuropathy remains the electrodiagnostic examination. Nerve conduction studies focus on sensory, motor, and mixed nerve function in the distribution of symptoms or lesion. Evidence of focal demyelination includes prolongation of distal latencies or slow/absent conduction. In axonopathy, amplitudes of the evoked response are low or absent.

**TABLE 29.10 Mononeuropathies: Diagnostic and Treatment Considerations****Diagnosis**

1. Clinical presentation suggestive of peripheral nerve entrapment/compression syndrome: history and physical examination
2. Electrodiagnostic confirmation of a nerve segment lesion
3. Correlate history, physical examination, and electrodiagnostic findings
4. Electrodiagnostic excludes radiculopathy, plexopathy, or peripheral polyneuropathy

**Treatment**

1. Avoid or modify aggravating activities—ergonomic modifications
2. Treatment of underlying medical conditions
3. Splinting—resting splints: to minimize nerve compression secondary to joint position, muscle/tendon overuse, or stretch of the nerve
4. Minimize external compression
5. Orthotic devices to restore joint motion or position—generally, ankle and foot
6. Reduce swelling and/or edema
7. Anti-inflammatory and/or pain medications
8. Corticosteroid injection
9. Physical therapy: modalities, massage, exercise
10. Surgical decompression or transposition of nerve

The electrodiagnostic exam is valuable for both diagnosis and prognosis. Nerve conduction studies may be normal until Wallerian degeneration takes place. Neurapraxia is unlikely if sensory conduction remains absent after 7 to 10 days. Table 29-11 summarizes electrodiagnostic findings following nerve injury.

Magnetic resonance imaging (MRI) studies are also used to diagnosis peripheral nerve injury (9). Visible changes can be detected by MRI at about the fourth postinjury day. MRI has good sensitivity and specificity, especially on the short-tau inversion recovery signals for axonotmetic or neurotmetic lesions. Neurapraxia yields normal findings. Magnetic resonance neurography and even plain films for associated injuries, such as fracture or dislocation, may be useful.

Laboratory screening can be helpful to identify the etiology of peripheral neuropathy. Routine studies include serum glucose, hemoglobin, leukocytes, platelets, erythrocyte sedimentation rate, thyroid studies, creatinine, and serum protein electrophoresis.

## TREATMENT STRATEGIES FOR PERIPHERAL NEUROPATHY

Treatment options for peripheral neuropathy include treatment of underlying disease, splinting, medication, therapeutic modalities, stem cell therapies, and surgery (Table 29-12).

Multiple agents have been studied for modifying peripheral neuropathy itself through genetic or direct effect. They might enhance nerve cell survival, promote neural anabolism, reduce oxidative stress, or delay apoptosis. Their value is unclear. Human or animal studies have been generally inconclusive to date (100–107). These agents are listed in Table 29-13.

Stem cell therapy is becoming an increasing valuable tool to encourage peripheral nerve healing. There is evidence in both rats and humans that myelinating Schwann cells can be obtained by seeding with marrow stem cells (recovery from pain and sensory nerve function) or mesenchymal stem cell seeding (animal model). Human amniotic mesenchymal stem

**TABLE 29.11 Electrodiagnostic Findings After Nerve Injury**

Condition	Insertional Activity	Activity at Rest	Fibrillation Potentials	Positive Sharp Waves	Shape	Interference Pattern

**TABLE 29.12** Rehabilitation Management of Peripheral Neuropathy

Problem	Functional Consequence	Rehabilitation Intervention
Weakness	Proximal Distal	Rising from chair, jumping stairs Foot drop/slap, poor toe clearance Ankle sprains, loss of dexterity and fine motor control
Generalized weakness and deconditioning	Loss of endurance	PREs AFO, UCBL, splint, functional orthosis, tool or equipment modification
Distal sensory loss	Loss of proprioception, imbalance, impaired fine motor control	GCEs Education in energy conservation Fine motor exercises Assistive device (e.g., cane)
Impaired motor control	As above	
Autonomic dysfunction	Abnormal sweating, cold intolerance	Educate regarding gloves, clothing, antiperspirant
Pain	Decreased activity	Analgesics, TNS, surgery
Deformity		Foot orthotics, bracing, surgery

cells can improve growth of a peripheral nerve across any gap in continuity (108–111).

Treatment of underlying disease also addresses conditions that lead to fluid retention or thickening of tissues surrounding a nerve. There may be a need to correct nutritional deficiencies, eliminate toxic exposure, or suppress an immune response.

Splinting is useful for restricting joint or tendon motion and reducing intermittent pressure on the nerve. Strategies that mobilize tissues and reduce adhesions (massage, ultrasound, exercise) are useful in entrapment neuropathies before considering surgical release.

### Treatment of Pain

Medications, local anesthetic or corticosteroid injection, and transcutaneous nerve stimulation are the most frequent methods of addressing peripheral nerve pain. Similar strategies are used for the chronic neuropathic pain that can follow an acute painful peripheral neuropathy.

Medications used to manage pain include tricyclic antidepressants, selective serotonin/serotonin-norepinephrine reuptake inhibitors (SSRI, SNRI), nonsteroidal anti-inflammatory drugs (NSAIDs—including transdermal preparations), opiate agonists, topical counterirritants, topical capsaicin, stimulatory peptides, and anticonvulsant or antispasticity agents (111).

Anticonvulsants modulate sodium channels and suppress ectopic or ephaptic discharge in neuropathic pain. Gabapentin and pregabalin have demonstrated efficacy in decreasing pain, improving sleep, and enhancing mood and quality of life for patients with postherpetic or diabetic neuropathy.

Antidepressants are helpful in pain-related depression, and both the tricyclic and the SNRI medications show some efficacy in treating pain. Stimulatory peptides (short-chain amino acids derived from cytokine proteins or growth factors) encourage healing, alleviate pain, and may prevent neuron death (112).

Transcutaneous electrical stimulation (TENS), pulsed galvanic stimulation, and heat and cold modalities (113–116) are useful nonpharmacological means of providing analgesia. Mobilization of a painful limb segment and normal use of a limb is important, particularly as chronic regional pain syndromes may complicate a peripheral neuropathy (117).

**TABLE 29.13** Agents With Possible Effect on Peripheral Neuropathy

Neurotrophic growth factors	Ciliary neurotrophic factor (CNTF) Brain-derived neurotrophic factor (BDNF) Glial cell line–derived neurotrophic factor (GDNF) Recombinant human insulin-like growth factor

### PERIPHERAL NERVE REPAIR FOLLOWING TRAUMA

The ability of the peripheral nerve to recover from trauma, including both injury and subsequent repair, depends upon a variety of intrinsic and extrinsic factors. When the cell body is viable, the peripheral nervous system demonstrates a great capacity for recovery, beyond that of the central nervous system. This capacity is facilitated or inhibited by intrinsic

factors such as age, state of tissue nutrition, time since injury and type of injury, the specific peripheral nerve involved, and the level of lesion. In general, well-nourished younger patients with recent injury that is located at the distal nerve trunk do better. Similarly, extrinsic factors such as medical treatment and surgical and postoperative management may enhance or inhibit healing (9).

Negative prognosticators for successful nerve repair include advanced age, nerve injury due to dislocation, delay of repair beyond 5 months, prior radiation therapy, nerve discontinuity (gap) exceeding 2.5 cm, proximal nerve injury, and a poor condition of the nerve endings (6). Sensation may improve as late as at 2 years following repair.

Initially, surgery may be exploratory in order to establish an accurate diagnosis when the clinical and electrodiagnostic examinations are inconclusive. Exploratory surgery exposes the extent and severity of the lesion. Surgery may also be considered when there is an incomplete loss of function but no improvement over several weeks or no return of function at about 2 months after injury (4 months for the brachial plexus). The purpose of surgical repair is to improve peripheral nerve recovery and eventual function—if the prognosis for this is poor, surgery should not be done.

There are two basic approaches to reestablishing nerve continuity: macrorepair (reconnecting the nerve ends by epineurial suture) and microscopic (this consists of suturing individual nerve bundles) (118). Surgery is only done when there is adequate length of a viable nerve. Repair is done for Sunderland grade 3–5 lesions. Early repair is desirable, as maximal nerve regeneration occurs at about 3 weeks after injury (7).

Immediate or primary repair is performed within 8 to 12 hours on clean lacerating injuries. Delayed or secondary repair, which is more usual following major trauma, blunt transection or wound contamination, or complete neurotmesis without clear nerve endings, is performed after more than 1 month. This delay in repair allows better definition of the lesion and a reduced risk of infection.

Macroneurorrhaphy, reestablishing the continuity of the epineurium, remains the standard surgical repair. Epiperineurial repair, fascicular or perineurial nerve repair, and interfascicular nerve repair are also done, but there are insufficient data that demonstrate a better outcome from this type of surgery. Fascicular groups must be large enough to anchor sutures, and proper tensioning of the repaired nerve is essential (119).

Placement of a peripheral nerve graft is done when the resected nerve segment produces a gap between nerve endings greater than 2 cm (120). Resorbable nerve conduits seem to work well following neuroma resection, but not for nerve repair (Meek, Nicolai, Robinson). Neurolysis may be needed to remove scar tissue. In order to bridge a gap in nerve continuity, surgical alternatives to grafting include nerve mobilization, nerve transposition, tissue expansion (121), joint flexion, tubulization (with or without Schwann cell-seeded collagen matrix in the conduit), and bone shortening (122).

Trophic factors that enhance nerve regeneration through a graft or tube include neurocytokines (NGF), brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor, and neurotrophin-3, -4, -5, and -6 (123,124). Trophic factors work by preventing fibroblast activity and inhibiting protease activity.

After surgery, passive and active range of motion of related joints is begun and splinting (12t) is provided as necessary. Hyperbaric oxygen therapy decreases endoneurial edema, pressure, and vascular compromise in ischemic lesions (87).

There is some controversy regarding early passive mobilization following surgery. Most commonly, the operated limb is immobilized for 4 to 6 weeks, apart from providing limited range of motion to prevent or limit joint contracture (125). Early tactile stimulation may enhance recovery of sensory function (122).

Conditions that can complicate the postoperative course include chronic pain syndromes, neuroma formation, peripheral nerve entrapment syndromes, complex regional pain syndromes type 1 and 2, weakness, sensory loss, and atrophic skin changes. If neurosurgery fails, tendon transfers can sometimes offer the patient a partial restitution of function.

Remaining current regarding related research and applications allows the physiatrist to guide patients with pain, weakness, and/or disability due to peripheral neuropathy to optimal rehabilitation outcomes.

# Myopathy

Representing a diverse group of disorders primarily affecting skeletal muscle, myopathies are an important cause of disability affecting patient mobility, self-care, and independence. In addition to weakness, many myopathies have associated dysfunction in other organ systems, such as the cardiac and pulmonary systems. The disability associated with muscle disease depends on the specific type, extent of clinical involvement, and rate of progression.

The number and type of different muscle disorders under the umbrella term myopathy are vast and expanding. With our increasing knowledge about genetic and molecular basis for these disorders, classification and nomenclature regarding myopathies are constantly being reevaluated and modified. A detailed discussion of all the different myopathies is beyond the scope of this chapter; however, this chapter is intended to provide the physical medicine and rehabilitation specialist with an overview of diagnostic approach, clinical characteristics, and care and management of patients with myopathies, with emphasis on few of the most common diagnoses that a physiatrist may encounter.

Although most myopathies remain largely incurable, as is the case for most neuromuscular diseases at this time, they are not untreatable. Rehabilitation specialists have an important role in the care of patients with myopathies to maximize their functional capacities, prolong or maintain independent locomotion and function, prevent physical deformity and medical complications, and provide access for integration into the community with quality of life in mind. The comprehensive management of all the varied clinical problems associated with myopathies and other neuromuscular diseases often requires specialists from neurology, cardiology, pulmonology, and orthopedic surgery as well as clinical specialists in physical therapy, occupational therapy, speech therapy, and orthotics. Coordination of this difficult and demanding task may be best handled by a neuromuscular and rehabilitation medicine specialist knowledgeable in various myopathies. It is important for the rehabilitation physician to understand these diseases in order to appropriately treat the functional problems caused by muscle weakness as well as provide comprehensive interdisciplinary rehabilitation through awareness of other manifestations of the disease.

## DEFINITION AND CATEGORIES OF MYOPATHY

In the peripheral nervous system, a primary defect may occur at the level of the anterior horn cell, peripheral nerve, neuromuscular junction, or muscle. A disease process in which

the primary abnormality is at the level of the muscle itself is termed *myopathy*. A brief overview of the various myopathies is presented in this section to help the reader classify numerous myopathies in an orderly fashion. A more detailed discussion of the individual myopathies pertinent to rehabilitation specialists is found in the subsequent sections.

There are three basic categories of myopathy: hereditary, acquired, and myopathies associated with systemic disease (Table 30-1). In the *hereditary myopathies*, all of the myopathies have their inheritance pattern characterized or gene mutations identified. This category of myopathy is further subdivided into muscular dystrophies, congenital, distal, metabolic, and mitochondrial myopathies. In general, the muscular dystrophies present with significant structural defect of the muscle cell due to mutations in genes crucial for its normal function. Typically, the muscular dystrophies are accompanied by progressive muscle fiber degeneration, atrophy, and inflammation as noted by histopathological evaluation. The specific muscular dystrophies that are more commonly encountered, with its characteristic inheritance pattern, affected genes or mutations are listed (Table 30-2). Congenital myopathies are a group of relatively nonprogressive muscle diseases that present during infancy or early childhood and are classified largely based on clinical features and muscle biopsy morphological findings. Distal myopathies, as the name implies, have more pronounced weakness involving distal limb muscles rather than the typical proximal weakness seen with majority of other myopathies. Metabolic myopathies are caused by gene mutations that result in either abnormal glycogen or lipid metabolism. Usually, deficiency of an enzyme results from a gene mutation and causes an abnormal accumulation of substrate or a deficiency of the product of the enzymatic pathway. Mitochondrial myopathies are a group of muscle disorders with maternal inheritance pattern associated with abnormal structure and function of mitochondria. Since mitochondria are important in energy production throughout the body, other organ system involvements are also common including the nervous, cardiac, gastrointestinal, pulmonary, and endocrine systems. Diagnosis is often based on a combination of clinical findings and associated biochemical defects, along with histological abnormality noted as “ragged red fibers” on the modified Gomori trichrome stain. Another group of myopathies called channelopathies include primary muscle disorders caused by inherited abnormalities of various ion channels found on cell membranes. These include myotonia congenita, paramyotonia congenita, and primary hyperkalemic and hypokalemic periodic paralysis.

**TABLE 30.1      Myopathies**

Hereditary Myopathies	Acquired Myopathies
<i>Muscular dystrophies</i>	<i>Inflammatory myopathies</i>
Duchenne muscular dystrophy (DMD)	Polymyositis (PM)
Becker muscular dystrophy (BMD)	Dermatomyositis (DM)
Myotonic muscular dystrophy (DM1 and DM2)	Inclusion body myositis (IBM)
Facioscapulohumeral muscular dystrophy (FSHD)	<i>Toxic myopathies</i>
Limb-girdle muscular dystrophy (LGMD)	Corticosteroid myopathies
Congenital muscular dystrophy (CMD)	Lipid-lowering agent myopathies
Oculopharyngeal muscular dystrophy (OPMD)	Alcohol-related myopathies
Emery-Dreifuss muscular dystrophy (EDMD)	Myopathies related to other medications
<i>Congenital myopathies</i>	<i>Endocrine myopathies</i>
Central core, nemaline, centronuclear, multicore	Myopathies with glucocorticoid abnormalities
Fiber type disproportion, reducing body	Myopathies with thyroid disease
Fingerprint, cytoplasmic body, myofibrillar	Myopathies with parathyroid disease
<i>Metabolic myopathies</i>	Myopathies associated with pituitary dysfunction
Disorders of glycogenoses	Myopathies related to electrolyte disturbance
Disorders of lipid metabolism	<i>Infectious and granulomatous myopathies</i>
Respiratory chain defects	Viral, bacterial, fungal, tuberculous, parasitic
<i>Distal myopathies</i>	Sarcoid myopathy
Welander, Markesbery-Griggs-Udd, Nonaka, Miyoshi, Laing	<i>Myopathies associated with systemic disease</i>
<i>Mitochondrial myopathies</i>	Critical illness myopathy
Kearns-Sayre's syndrome, Progressive External Ophthalmoplegia (PEO)	
Mitochondrial Encephalomyopathy Lactic Acidosis Stroke (MELAS)	
Myoclonic Epilepsy Ragged Red Fibers (MERRF)	
Neuropathy Ataxia Retinitis Pigmentosa (NARP), Myopathy and external ophthalmoplegia Neuropathy Gastro-Intestinal Encephalopathy (MNGIE)	
Leber's Hereditary Optic Neuropathy (LHON), Leigh's syndrome	
<i>Channelopathies</i>	
Myotonia congenita	
Paramyotonia congenita	
Primary hyperkalemic and hypokalemic periodic paralysis	
	Electrolyte disturbances
	Paraneoplastic

[illegible]

Muscular Dystrophies	Inheritance Pattern	Gene Loci	Gene (Mutations)
DMD	X-linked	Xp21	Dystrophin
BMD	X-linked	Xp21	Dystrophin
DM1	AD	19q13.3	DMPK (expansion of CTG repeat)
DM2	AD	3q21	ZNF9 (expansion of CCTG repeat)
FSHD	AD	4q35	DUX4 (deletions of D4Z4 repeats)
LGMD (type 1s)	AD	Multiple loci	Myotilin, laminin A/C, caveolin-3
LGMD (type 2s)	AR	Multiple loci	Calpain-3, dysferlin, sarcoglycans, Fukutin-related protein (FKRP)
OPMD	AD or AR	14q11.2-q13	PABN1 and PABP2 (Polyadenylate-binding protein, Nuclear) (expansion of GCG repeat)
EDMD 1	X-linked	Xq28	Emerin
EDMD 2	AD	1q21.2	Laminin A/C
CMD	AR	6q22	Merosin

AD, autosomal dominant; AR, autosomal recessive.

The second category, *acquired myopathies*, consists of inflammatory, endocrine, toxic, granulomatous, and infectious myopathies. Under inflammatory myopathies are polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM). Muscle disorders associated with various endocrinopathies are now well recognized. These include myopathies associated with thyroid dysfunction (hyperthyroidism or hypothyroidism), adrenal disease, pituitary dysfunction, and parathyroid dysfunction (hyperparathyroidism or hypoparathyroidism). Myopathies can also result from electrolyte disturbances, including abnormalities of serum potassium, sodium, calcium, magnesium, and phosphorus. Under the toxic myopathy category, the most common agents associated with myopathy include HMG-CoA reductase inhibitors (cholesterol-lowering agents), corticosteroids, fibric acid derivatives (lipid- and cholesterol-lowering agents), chloroquine and amiodarone (amphiphilic drugs), colchicine and vincristine (antimicrotubular agents), zidovudine (HIV medication), and alcohol. Of the toxic myopathies, alcohol-related myopathy is thought to be the most common with both acute and chronic manifestations, often associated with heavy and prolonged alcohol use. Although typically asymptomatic in terms of muscle manifestation, sarcoidosis can present in the form of a granulomatous myopathy. Lastly, infectious myopathies are associated with essentially all types of infectious agents including viral (coxsackievirus, HIV, HTLV-1), bacterial, fungal, tuberculous, as well as parasites.

The last category is *myopathies associated with systemic disease*. Under this category are myopathies that have significant systemic processes that result in derangement of muscle function and health. The most common etiologies are severe multiorgan failure with sepsis, electrolyte disturbances associated with systemic disease, and underlying neoplasms.

Clinical features and progression vary within and between these categories as pathophysiology of each muscle disorder is different. Some of the myopathies, partly due to their time course of progression, involvement of other organ systems, prevalence in the population, and the availability of rehabilitative treatment options, may be more or less pertinent to rehabilitation specialists. However, in order to devise an appropriate rehabilitation plan, the rehabilitation physician should understand the expected disabilities and prognosis associated with the specific cause of myopathy.

## EVALUATION OF THE PATIENT WITH SUSPECTED MYOPATHY

### History

The primary symptom of a patient with suspected myopathy is weakness, defined as a reduction in maximal force generated by a muscle or muscle group (Table 30-3). This weakness may be fairly acute or insidious. Because the weakness is typically in the proximal musculature, certain functional problems should alert the clinician to the possibility of myopathy: difficulty getting

**TABLE 30.3 Clinical Features and Laboratory Findings Suggestive of Myopathies**

Proximal symmetric weakness
Normal sensation
Normal or mildly diminished tendon reflexes
Elevation of serum CK
EMG demonstrating brief, low-voltage, polyphasic potentials
Normal nerve conduction studies
Muscle biopsy with muscle fiber necrosis and regeneration, with central nuclei

up from a chair or toilet seat, trouble descending and climbing stairs, or difficulty with overhead activities, such as dressing, grooming, or reaching cabinets (Table 30-4). Symptoms suggesting distal weakness, such as problems opening jars, may be prominent with certain myopathies. The symptom of muscle fatigue, defined as the inability to sustain a given level of force for a certain period, is often difficult to assess. Although it may be associated with myopathy, when fatigue is the predominant symptom, other pathologic processes, such as neuromuscular junction disease and upper motor neuron disease, are more likely.

Muscle pain, or myalgia, is a common presenting symptom, particularly in the inflammatory myopathies. However, the absence of pain should not distract the clinician from strongly considering the diagnosis of myopathy. When myalgias are the predominant symptom without demonstrated weakness, other disorders are more likely. History of myoglobinuria associated with weakness or fatigue symptoms should be sought and can help in the workup of muscle disorders, especially the metabolic myopathies. The presence of paresthesias or dysesthesias on history is certainly helpful, because they make the presence of myopathy very unlikely. A rare patient might interpret myalgias with descriptors sounding like sensory symptoms, distracting the clinician.

One of the most critical pieces of information is the family history. Whenever a myopathy is suspected that may have a genetic cause, a detailed family history and pedigree chart are essential. In an X-linked recessive disorder such as Duchenne

**TABLE 30.4 Key Historical Questions for Suspected Myopathy**

Does the patient relate difficulty with climbing or descending stairs, squatting, rising from a chair, or managing overhead activities?
Is there a family history of weakness or unexplained use of a wheelchair?
What is the developmental history in terms of birth, motor milestones, keeping up with peers as an adolescent, or difficulty with school physical education?
Is myalgia or fatigue the primary symptom or secondary to the motor weakness?

muscular dystrophy (DMD), men on the maternal side of the family are affected about 50% of the time and women are carriers in an equal percentage. Autosomal recessive disorders, such as many limb-girdle syndromes, frequently have no family members involved, making the diagnosis of a familial disorder more difficult. In an autosomal dominant disorder such as myotonic muscular dystrophy or facioscapulohumeral dystrophy (FSHD), typically 50% of offspring within a pedigree are affected. Sporadic cases resulting from new genetic defects occur with most autosomal dominant and sex-linked dystrophies, making a dystrophy possible even in the absence of a suspicious family history.

In a child presenting with weakness, a developmental history should include milestones of age for head control, independent sitting, standing, and walking. Additional factors related to ambulation include toe walking, excessive lordosis, falls, and running ability.

### Physical Examination

Examination of the patient with suspected myopathy begins with observation (Table 30-5). In myopathies, muscle atrophy may not be obvious until late in the disease because of a wide normal range of variation in the population and the typical symmetry of muscular involvement. Calf enlargement may be noted in dystrophic myopathies, particularly in DMD and Becker muscular dystrophy (BMD). This “pseudohypertrophy” is caused by increased fat and connective tissue volume, rather than muscle fiber hypertrophy (1) (Fig. 30-1). Observation of facial features, such as a long thin face with temporal and masseter wasting with frontal balding, is typical for myotonic muscular dystrophy.

Other physical examination findings that may be particularly helpful in the evaluation of myopathies are the presence and distribution of rash, contractures, and ligamentous laxity. These may be useful when considering diagnoses such as DM, Emery-Dreifuss muscular dystrophy (EDMD), and muscle diseases with associated collagen dysfunctions. Cardiac examination is also important as some myopathies have an associated conduction abnormality or a cardiomyopathy. Examination of the pulmonary system can provide clues to an accompanying restrictive lung disease process or an aspiration pneumonia secondary to swallowing difficulties.

Because weakness is the predominant symptom, determination of muscle strength is critical. Unfortunately, the manual muscle test typically used by clinicians is only a very rough measure of strength. It is well known that up to 50%

**FIGURE 30-1.** Calf pseudohypertrophy in an 8-year-old boy with DMD.

strength loss may occur before a muscle is graded as 4/5 using the Medical Research Council (MRC) scale (2). The more powerful pelvic proximal muscles are particularly difficult to measure, because the patient should be able to overcome the examiner’s resistance. The handheld dynamometer is a quantitative device to measure strength, but it shares the same limitation when strong muscles are being tested. It has been shown to provide reliable data in persons with neuropathic weakness (3). Because of a wide range of normality, the handheld dynamometer is probably better suited to measure serial strength than to quantify a specific muscle group as “normal” or “abnormal.”

Probably the most reasonable method to test strength in the clinic is to observe repetitive maneuvers, such as rising from a squat, repeatedly standing on the toes, or raising the arms overhead with resistance. The clinician should observe for Gowers’ sign: The patient rises from a low surface by pushing against the knees and moving the hands up the thighs to substitute for knee and hip extensor weakness.

Facial and neck muscle weakness predominates in several myopathies such as FSHD. The ability to “bury” the eyelashes or the ability of the examiner to easily overcome forced eye closure (because of orbicularis oculi weakness) and difficulty whistling (because of orbicularis oris weakness) are reasonable screening tests. The presence of ptosis or ophthalmoplegia

**TABLE 30.5** Key Physical Examination Points for Suspected Myopathy

Proximal > distal weakness, including neck and facial muscles
Observation of facial features
Sensation—should be normal
Muscle tendon reflexes preserved or mildly decreased
Presence of clinical myotonia
Waddling gait with Gowers’ sign on standing
Positioning of the shoulder girdle

should also be noted. The neck flexor muscles are usually much more affected than the neck extensors and are the earliest muscle group to show abnormality in DMD (4).

Myotonia, a state of delayed relaxation or sustained contraction of muscle, is common to the myotonic muscular disorders. Action myotonia may be demonstrated by asking the patient to grip the examiner's fingers tightly and then quickly attempt to relax. Extension of the fingers will be difficult. Alternatively, percussion myotonia may be elicited by tapping the thenar eminence with a reflex hammer, causing a local involuntary contraction of the thenar muscles. Muscle tendon reflexes are generally preserved in myopathies until there is profound loss of strength, an important differentiating factor from neuropathic disorders.

Careful observation of gait is very helpful in evaluation of the patient with myopathy, and a classic pattern of gait progression may be noted in progressive dystrophic myopathies. One of the earliest features in patients with myopathy is hyperlordosis of the lower back, a compensation for hip extensor weakness by maintaining the weight line behind the hip joints. Waddling is typical during gait because of weakness of the hip abductor musculature, resulting in the necessity to bring the trunk over the weight-bearing limb during stance phase, the so-called "gluteus medius lurch." When knee extensor weakness becomes significant enough to cause knee buckling, the ankle is postured into progressive plantar flexion, producing a knee extension moment at heel strike and positioning the weight line anterior to the knee during later stance, which stabilizes the knee. This pattern predominates in DMD and BMD. In other myopathies, "back knee" or genu recurvatum during stance phase provides stability by bringing the weight line in front of the knee joint. In the unusual myopathy in which distal weakness predominates, such as myotonic muscular dystrophy and an occasional FSHD, weakness of the ankle dorsiflexors and evertors occurs early. These patients may ambulate with steppage gait and foot-slap at floor contact, very similar to the neuropathic disorders.

Positioning of the shoulder musculature and scapulae may be helpful in discerning myopathy. In FSHD and limb-girdle muscular dystrophy (LGMD), involvement of the latissimus dorsi, lower trapezius, rhomboids, and serratus anterior results in superior and lateral displacement of the scapula, giving the shoulders a forward-sloped appearance. There is associated scapular winging of the medial border, and the upward positioning of the scapula into the trapezius can mimic hypertrophy of this muscle.

### Laboratory Evaluation

The most important blood study for suspected myopathy is measurement of serum creatine kinase (CK). With muscle fiber injury, this enzyme leaks into the serum. Particularly high elevations of CK (50 to 100 times normal) may be found in acute inflammatory myopathies and the early stages of DMD and BMD. The more slowly progressive dystrophies may have mild to moderate elevations in CK. However, CK is not the ideal screening test for all myopathies because the congenital myopathies, slowly progressive dystrophies, chronic inflammatory myopathies, and myopathies of systemic disease may

have normal values. The clinician should be cautious not to overinterpret one mildly elevated CK level, because it may be elevated in healthy persons for several days after vigorous exercise. Conversely, once there is significant muscular atrophy, CK values may be low or normal based on the paucity of remaining muscle tissue to release the enzyme. Other serum transaminases, aldolase, and lactate dehydrogenase are often elevated in myopathy but are much less specific because they are found in liver in equally high amounts. In the metabolic myopathies, measurement of blood lactate and pyruvate may be helpful, particularly arterial lactate levels during ischemic or exercise stress. With abnormalities of glycogen metabolism, there will be no rise in lactate because patients cannot catabolize glycogen.

### Electrodiagnosis

Electrodiagnostic studies (electromyography [EMG]) can be extremely important in the evaluation of the patient with myopathy to localize the pathology to the muscle rather than nerve or anterior horn cell. The pattern of EMG findings may indicate the best muscle for biopsy, and certain abnormalities on the EMG occasionally suggest a specific myopathic disease. However, electrodiagnostic studies in myopathy may be normal as well, so a myopathic disorder is not ruled out by normal EMG studies.

Nerve conduction studies should be normal in myopathic disorders, with the exception of a low compound motor action potential obtained when recording over muscles with severe atrophy. With needle EMG, the presence of abnormal spontaneous activity (positive sharp wave/fibrillation potentials) is dependent on whether the myopathy is causing active muscle fiber degeneration. For example, the inflammatory myopathies and rapidly progressive dystrophies frequently demonstrate abnormal spontaneous activity, whereas it is not often encountered in the slowly progressive dystrophies or myopathies associated with systemic disease.

The hallmark needle EMG finding suggesting myopathy is the presence of low-amplitude, often polyphasic, brief-duration potentials with voluntary contraction. Because recruitment of each additional motor unit only slightly augments strength, the electromyographer often notes an excessive number of motor units for a given strength of contraction. These findings may be subtle or absent, particularly in slowly progressive disorders. Particularly important muscles to evaluate with possible myopathy include the paraspinal, supraspinatus and infraspinatus, glutei, and iliopsoas muscles.

### Muscle Biopsy

The ideal muscle for biopsy is weak, but not profoundly atrophic. Electrodiagnostic abnormalities increase the likelihood that the muscle will demonstrate useful findings, although one should not biopsy a muscle that has recently been evaluated with a needle electrode because of possible needle-induced fiber damage. The most accessible muscles include the vastus lateralis in the lower limb and the deltoid or biceps brachii in the upper limb. Histologic findings suggestive of myopathy include fiber necrosis, central nuclei indicative of regeneration, atrophied fibers, inflammatory infiltrates, and proliferation of connective

tissue and fibrosis. Certain congenital myopathies, including centronuclear or myotubular, central core, and nemaline rod, have distinctive histologic and electron microscopy findings. In addition to histologic studies, immunohistochemical techniques can provide information about the amounts of dystrophin and other structural membrane proteins.

### Molecular Genetic Studies

Recent advances in molecular genetic techniques have resulted in remarkable increases in the knowledge of various myopathies. The chromosomal location, causal gene, and mutations have been identified in many neuromuscular disorders and are frequently helpful in diagnostic evaluation. An example of the impact of molecular genetic studies is the evaluation for possible DMD or BMD. Both disorders are caused by mutations in an extremely large gene located on the X chromosome. The protein product of the gene, known as *dystrophin*, was determined to be an important component of the muscle membrane cytoskeleton, contributing to the stability of the muscle fiber (5). For diagnosis, a clinically available gene deletion study from a blood sample is diagnostic of a dystrophinopathy, but it is able to detect mutations present in only about 65% of DMD patients and 80% of BMD patients. Additional DNA analysis to detect smaller mutations in the dystrophin gene increases the detection rate to approximately 90% of patients with DMD (6). However, a positive test does not clearly distinguish between DMD and BMD. A muscle biopsy for immunohistochemical analysis of the dystrophin protein is necessary in patients testing negative for the mutation or to differentiate between a patient with a particularly severe form of BMD versus a patient with a milder form of DMD. Absent dystrophin or levels less than 3% is consistent with DMD whereas in BMD, the dystrophin may have an abnormal molecular weight or decreased in quantity.

The number of commercially available genetic tests has grown tremendously over the past several years and continues to expand. In addition, there are numerous research laboratories that specialize in specific myopathies and can even offer genetic testing for research purposes, when commercial tests are not available. A list of clinical and research laboratories offering genetic tests for various myopathies or neuromuscular disorders can be found at: [www.genetests.org](http://www.genetests.org). Although genetic tests occupy an important place among diagnostic tools now available to a clinician, it should not replace a careful history, thorough physical examination, and clinical common sense in the evaluation of a patient with myopathy.

## CLINICAL FEATURES OF SPECIFIC MYOPATHIC DISORDERS

### Dystrophic Hereditary Myopathies Duchenne Muscular Dystrophy

DMD is an X-linked disorder with the chromosomal abnormality at the Xp21 gene locus (7). As noted above, the gene codes for the protein dystrophin, an important cytoskeletal

component of the muscle cell membrane. It appears that absence of dystrophin makes the muscle cell highly susceptible to mechanical stress, with eventual muscle fiber loss and replacement with fibrotic tissue (5,8).

DMD is the most common form of childhood muscular dystrophy, with an incidence of approximately 1:3,500 male births (9). Although a male inheritance pattern is typical, as many as one third of cases may be due to new mutations, without any previous family history. Typical initial symptoms include abnormal gait, frequent falls, and difficulty climbing steps. Hypotonia and delayed motor milestones occur in earlier onset cases, but in 75% to 80% of cases, onset is noted before age 4 (4). The abnormal gait is often noted by toe walking, which is a compensatory adaptation to knee extensor weakness, or increased lumbar lordosis as a compensation for hip extensor weakness. Another indication of pelvic girdle weakness is Gowers' sign, demonstrated as the child rises from the floor. The patient generally begins by assuming a four-point stance, then brings the knees into extension while leaning the upper limbs forward, and sequentially moves the hands up the thighs until upright stance is achieved (Fig. 30-2A–D).

On examination, the earliest weakness is seen in the neck flexors, typically during the preschool years. Weakness of the proximal musculature of the shoulder and pelvic girdle is next, with steady progression, although the patient and family may feel that functional loss does not occur gradually but rather quite suddenly. This may relate to a critical point in weakness or range of motion when compensatory actions can no longer suffice to perform a task. Quantitative strength testing shows greater than 40% to 50% loss of strength by age 6 years (4), with fairly linear progression from ages 5 to 13 measured by manual muscle testing. Weakness appears to plateau after age 14 to 15, but this is probably a function of a floor effect and lack of sensitivity of the manual muscle testing scale (10,11).

Rehabilitation concerns are summarized in Table 30-6. In patients not aggressively treated, the average age to wheelchair use is 10, with a range of 7 to 13 years of age. Prediction of transition to wheelchair use may be helped by using timed motor performance tests. In one natural history study, all DMD subjects who took more than 12 seconds to ambulate 30 ft lost the ability to ambulate within 1 year (4). Immobilization, even for an acute illness, may lead to permanent loss of ambulatory ability during this phase of the disease.

**TABLE 30.6 Rehabilitation Concerns in DMD**
